Progress: History of the Concept

Abstract

Extension of the progress of science into the realm of government and morals was central to Enlightenment belief in historical progress. During the nineteenth century, progress provided the framework and central problem of social science theory, and belief in the progress of the social sciences became the ideology of the social science disciplines. Discontents with progress had been present from the start and the conviction that progress was inevitable collapsed in the twentieth century, although in mitigated forms, it waxed and waned with historical expectations. At the end of the century, postmodern sensibilities challenged the progress both of history and the social sciences.

The idea of progress – that "civilization has moved, is moving, and will move in a desirable direction" (Bury, 1932) – was integral to the project of creating social sciences in eighteenth century Europe, and the relationship has continued since. During the nineteenth century, the idea of progress formed the historical framework and central problematic of social science theory and practice. One component, the idea of the progress of the social sciences figured prominently as the ideology of the social science disciplines. From its origin, however, the idea of progress was accompanied by recognition that progress created new problems and by doubts that the modern world coming into existence would be superior to the past or present. The belief that progress was inevitable collapsed in the disasters of the twentieth century, although belief in the possibility of progress continued in mitigated forms, waxing and waning with the portent of historical events, the expectations of different national cultures, and the character of the social sciences.

This article embraces a theoretical tension that runs through recent studies of the human and social sciences. The project of creating social sciences was both a shared idea, aspiration, or program aimed at social improvement by means of science; and a framework, a mode of understanding the world within which certain kinds of ideas and practices rather than others came into being. In this latter sense, the program of science aimed at social improvement was a set of possibilities and constraints within which the social sciences formed. In the spirit of this duality, studies of the social sciences have emphasized the importance of language as both speech act and the medium in which meanings are produced, especially those integrated bodies of language called discourses that form from extended conversations around a shared problem. A discourse provides a bounded language for varied semantic use. Variant discourses of progress were the medium within which social scientists formed their purposes and within which they represented those purposes as true and legitimate (Porter and Ross, 2003).

Eighteenth-Century Origins

The discourse of progress and the social science project emerged in early modern Europe as part of a new understanding of history as a realm of human construction, propelled ever forward in time and taking new qualitative forms. Modern society was decisively different from its feudal and ancient forerunners, engaged upon a novel historical course. Replacing earlier cyclical and supernatural views of historical time, historicism instantiated in human history the teleological movement and universal scope that governed the Christian drama of redemption. During the eighteenth century, enlightened thinkers argued that the advance of reason was moving history in a progressive direction, even to a utopian end. The emergence of the social sciences was itself a linchpin of progress. Science was understood as the most advanced form of reason, and the extension of the progress of science into the realm of government and morals – barely begun – was central to the expectation of civilizational advance. The array of human differences across the globe also sharpened for European thinkers the progressive character of their own society and the stages by which they had reached modernity (Meek, 1976). The task of the social sciences was to understand the forces that governed the modern European world and to guide it into a better future.

The eighteenth-century discourse of progress drew upon, and was often coincident with, the early formulations of social science. Associationist psychology explained the ability of human mental capacities to improve over time, while the studies of historians and economists and the observations of travelers set the trajectory of progress toward greater complexity and refinement with increasing social differentiation and intercourse came improving manners, morals, knowledge, and rationality. The guiding role of providence in this process was still visible, but it was understood to work through nature. Particularly in Britain and France, natural principles assured the existence and continuation of progress.

Several major theories of progress emerged within this discourse. Scottish 'philosophical historians' like Adam Smith and Adam Ferguson developed four- or five-stage theories of history in which the economic mode of production at each stage shaped political organization, customs, and moral temper. Economic growth, fueled by the expansion of population, the division of labor, and technological advance, emerged within a complex social process, for history was often the result of unintended consequences. In contrast, the philosophers of the French Enlightenment like Condorcet focused on reason as the overriding factor in historical progress.

The rational acts of enlightened individuals, and particularly of utilitarian science, moved humanity forward, ignorance and war held it back. In Germany, Herder and Kant made historical progress the work of philosophical and moral reason. History was the progressive fulfillment of humanity's moral and spiritual destiny, realized through the unique development of each historical people.

Emerging in contested political arenas, the early theories of progress staked out ideological positions of long-standing influence in politics and the social sciences. Designedly, Smith's social historical view lent itself to a liberal presumption against state action; Condorcet's, to a justification of the authority of social scientists in the guidance of society; Kant's, to a statecraft subordinated to idealist ends. Moreover, if the reliance on progressive reason initially assigned all evil to reactionary enemies, Scottish republicans and German idealists recognized from the start that progress necessarily involved losses. By the end of the eighteenth century, Rousseau's contention that progress in reason involved instinctual loss; Ferguson's analysis of the political, social, and psychological costs incurred by economic and social progress; Schiller's summation of these complaints into a 'classic diagnosis of the ills of modern society in terms of division, fragmentation, isolation, conflict, and distortion'– all drove a wedge between material and moral progress and set the foundation for a long line of variants on the discourse of historical advance that made progress itself responsible for the problems of modern society (Abrams, 1971: p. 211).

The Nineteenth-Century Triumph of Progress

Despite these misgivings, the American and French revolutions aroused millennial hopes throughout Europe and when the American Revolution succeeded and the French Revolution was destroyed from within and without, those hopes were projected into the secular future. The rapid advance of science and its technological adjuncts began to remake the Atlantic world, heralding an ever-improving future. Progress became the dominant view of history among the educated classes of Europe and North America, while contesting versions of progress proliferated. Responding to rapid capitalist development and the continuing possibility of political and social revolution, theorists of political economy, sociology, and anthropology recast the eighteenth-century theories of progress into social scientific discourses that specified the factors that controlled the course of history.

Classical political economy, drawing on the Scottish theorists, focused on the natural laws of economic growth and, of equal importance, on how the expanded product would be distributed. The question of whether the average workman would be better off, despite growing inequality, became urgent as egalitarian, utopian versions of progress appeared. The Reverend Thomas Malthus argued that food supply would keep wages at subsistence level. His political economy, informed by an Anglican reading of history, supported a cautious view of progress, incorporating cyclical movement and the necessity of suffering. The theories of David Ricardo were often pressed into this mold, though most practicing economists, including Ricardo, maintained a more hopeful account of economic growth based on capital accumulation. By midcentury, recognition of the role of technology in increasing productivity shifted the weight of economic opinion toward more optimistic predictions of future well-being (Berg, 1990).

American exceptionalists and socialist radicals transformed this liberal political economy in opposite directions. Henry C. Carey argued that the uncultivated American continent would abrogate altogether the action of Malthusian law, vindicating America's utopian historical course (Ross, 1991). Socialists, charging the capitalist economy with the degradation of workmen and the destruction of community, made capitalism an intermediate stage, to be superceded by socialism. In Karl Marx's formulation, history progressed by a process of historical contradiction between the forces and social relations of production: capitalism produced within itself the revolutionary proletariat that would destroy it and the technological basis of abundance that would support socialism and ultimately, communism (Cohen, 1978).

Auguste Comte, inheriting Condorcet's identification of historical progress with progress of the human mind, made social science its central agent. Civilization moved by necessary law from the theological to the metaphysical to the ultimate stage, the scientific, still struggling to be born. Although this trajectory was inevitable, action in accord with historical law could ease the transition. A new science of society, sociology, would objectively examine the world as it is and, based thereon, set out a plan for the rational ordering of society, opinion, and feeling (Lenzer, 1975). Herbert Spencer's version of sociology, influenced by liberal political economy and Scottish philosophical history, removed the central planning role from sociology, but gave it the same power to discern the laws of historical progress to which successful social action must conform. More complacent about his own era, Spencer believed that the industrial age would encourage moral, intellectual, and social improvement. Drawing on biological notions of adaptation to the environment, the inheritance of acquired characteristics, and an embryological model of differentiation, Spencer turned historical progress into an aspect of social and cosmic evolution (Peel, 1971).

Charles Darwin's *The Origin of Species* (1859) reinforced both the idea of progress and the use of biological analogy. Despite the radically nonprogressivist implications of natural selection, Darwin's theory, with its suggestion of the continuity of animal and human life, was often read in this era of faith in progress – even by Darwin himself – as proof of the progressive character of both evolution and history. The contemporaneous recognition of the long age of the earth created a space for 'prehistory,' solidifying the uniquely advanced position of European civilization (Bowler, 1989). Social scientists developed a 'comparative method' that sorted peoples and races on an evolutionary grid, assigning them to stages of a single evolutionary process by Euro-centered hierarchical standards.

Nineteenth-century Romantic critics of the Enlightenment discourse of progress also worked within its progressive secular conception of historical time. Even as they argued that analytical reason and the conventional society being created by economic development were destroying humanity's instinctual, aesthetic, and spiritual resources, they retained a vision of utopian possibility, available in the present to genius and in the future to all humanity through the creative imagination.

The Problem of Progress, 1880–1914

By the turn of the twentieth century, however, historical events and cultural criticism placed increased burdens on the belief in progress. The modernist heirs of romanticism often presented a dire picture of modernity as a desiccated world of mechanism, instrumental reason, and alienation. Even for those who continued to believe that the benefits of science and economic growth far outweighed their drawbacks, the problems created by rapid industrialization, mass democracy, and imperialism were multiplying. The social sciences formed specialized, university-based disciplines in large part to define and grapple with the problems of modernity. In that context, Enlightenment hopes for modernity took chastened forms. At the same time, more stringent conceptions of science outlawed deterministic laws of history like those of Comte and Spencer as metaphysical constructions and made the moral valuation inherent in the concept suspect. By the early twentieth century, the rediscovery of Mendelian genetics attenuated the link between evolutionary biology and historical change, and critics, notably anthropologist Franz Boas, attacked the comparative method and its assumption of a single line of evolutionary advance. Progress no longer appeared to social scientists as an inevitable, universal process, guaranteed by natural or historical law, but the assumption that history moved in a progressive direction remained deeply woven into the discourses of the social science disciplines.

In economics, marginalism shifted the focus of attention from economic growth to allocation. Those who joined the mixed neoclassical discourse grounded capitalism in laws analogous to the laws of physical nature and retained optimistic assumptions of economic growth and its central role in social advance, but those assumptions no longer framed their specialized and dehistoricized discourse. Other economists who sought a qualitative change in capitalism worked within a self-consciously historical or institutional framework, like the socialist Thorstein Veblen who asked in 1899 "Why Is Economics Not an Evolutionary Science?" (Ross, 1991).

The classic sociological theorists of this period took as their problematic the integration of individual and society and reduced the trajectory of history to two or three stages of modal social organization. In Germany, where antimodernist attitudes flourished, sociologists were most pessimistic. For Ferdinand Tönnies, traditional face-to-face community (*Gemeinschaft*) and modern capitalist society (*Gesellschaft*) marked polar modes of social organization. The impersonality and loss of spirituality of modern society were inevitable consequences of its organizing principles. Max Weber saw the positive advantages of the instrumental rationality and secularism that characterized modernity, yet termed the framework it built for modern society an 'iron cage' (Liebersohn, 1988).

Emile Durkheim, like American sociologists, retained the more hopeful nineteenth-century formulation that placed the present troubled society in transition to a more harmonious modernity. Durkheim argued that a new kind of functional and normative social integration was forming; the anomie of individuals thrown outside the regulative norms of society by the upheavals of social transformation would subside as modern society developed new forms of social solidarity. Edward A. Ross posited a transition from the natural social control of face-to-face community to the more fragile, 'artificial' controls of modern society, similar to the German model of *Gemeinschaft*/*Gesellschaft*, but he too expected that a more harmonious adjustment would be reached (Ross, 1991).

It was primarily in thinking about their own role in modern society that social scientists explicitly reaffirmed the central role of science in progress. In his presidential address to the American Psychological Association in 1899, John Dewey expressed both the anxieties of modernity and the solution favored by his colleagues. 'With tremendous increase in control of nature,' he noted, "we find the actual realization of ends, the enjoyment of values growing unassured and precarious." But, he added, "the entire problem is one of the development of science and of its application to life." When the social sciences are further developed, "we can anticipate no other outcome than increasing control in the ethical sphere" comparable to "the revolution that has taken place in the control of physical nature" (Dewey, 1976: pp. 149–150). That science itself progressed, that it produced increasing control over nature and social life, and that such control worked to the benefit of humanity remained unquestioned. This faith served as the ideological basis for the social science disciplines.

Progress Dethroned, 1914–50

The modern West's confidence in progress could not survive the massive destruction of the two world wars, the onset of economic depression, and the rise of totalitarian politics. Science and technology, hitherto proof of the progress of reason, were deeply implicated in these disasters. At the same time, a sharp sense of historical discontinuity, breaking off the new world of mass production, mass consumption, and mass politics from the past, destroyed the sense of cumulative gain in civilization on which progress depended. Historians mark World War I as the end of progress as an unquestioned public faith and as an idea that social scientists could presuppose or hope to demonstrate.

The toll on discourses of progress was greatest in Europe, which bore the brunt of the devastation and upheaval. Many threads of progressive theory were enfeebled or drawn into the orbit of totalitarian politics, as in Soviet Russia's Marxist–Leninist ideology of the revolutionary state and the 'new' man and woman. Other liberal and socialist variants of the discourse of progress survived in the Scandinavian forging of welfare states and in Austria's brief melding of empirical social science and socialist meliorism. Two notable efforts to sustain the possibility of progress despite dire views of the present were to have substantial influence during the second half of the century, particularly in the United States. In Austria and England, Friedrich Hayek – deploring the socialist direction of interwar economies – laid the foundation for neoliberalism in his *Road to Serfdom* (1944). And a group of mostly Jewish social theorists at the Frankfurt Institute for Social Research combined Marx's narrative of socialist progress and the modernist critique of capitalist society and culture. Exiled after 1933 to the United States, they found the basic source of modern evils in the radical separation of human beings from nature effected by modern science. The Enlightenment's objectification of nature objectified humanity itself, turning the human world into

a field for manipulation and political domination. Their vision of utopia no longer marked an historical future, but served only as a flickering standard by which to criticize the present (Jay, 1996).

The possibility nonetheless remained open, particularly in the United States, of constructing limited lines of progress and maintaining the hope that limited gains worked toward the larger progress of history. Thus the American sociologist William F. Ogburn explained that social scientists had dropped the term progress and were instead studying *social change* as a 'term free from dogmatic or moral implications.' Social change is caused by inventions, Ogburn argued, but inventions occur unevenly, creating 'lags' until society 'adjusts.' In his analysis, however, adjustments can always be made and adjustments always resulted in improvements. Progress was not so much abandoned as forced underground (Ogburn, 1930).

The point at which it remained still vibrantly alive, especially in the United States, was the faith in science. The neopositivist understanding of science itself suggested that science's pragmatic relation to reality allowed it to reconstruct the world to human purposes (Porter, 1994). While Ogburn was moderate in his hopes for prediction and control, other American social scientists of the 1920s, like the behaviorist psychologist John B. Watson and the political scientist Charles Merriam, expressed utopian faith in science and technology (Ross, 1991). Although a more sober tone emerged throughout the West in the 1930s, the possibility of historical progress through science remained a central feature of American social science theory and ideology.

Progress as Americanization, 1950–70

In the decades after World War II, the possibility of a progressive modern society guided by social science gained energy and urgency from the defeat of fascism, the disintegration of colonial empires, and the threat of communism. As the strongest power to emerge from the war, the United States embraced that possibility with a mixture of self-confidence and anxiety. In what was experienced as the 'American Moment' of an 'American Century,' the country already appeared to stand at the summit of world history, ready to embody the values its exceptionalist history promised. At the same time, Cold War challenges and the uncertainties of international leadership created palpable anxiety.

The discourse of progress continued to define the social science disciplines' hopes for modernity and their own central role. Both were explicitly embodied in modernization theory, which set out the distance the underdeveloped world still needed to traverse to achieve the Western, or more specifically American, norms of economic growth, democracy, and individualism (Gilman, 2003). Defined as a 'process of social change that seeks to govern itself by rational policy planning,' modernization declared social scientists' role in that process 'indispensable' (Lerner, 1968). During the same decades, University of Chicago economist Milton Friedman turned Hayek's complex arguments against state control of the economy into a simplified neoliberal ideology that promised a virtually utopian outcome to the organization of economy and society on free market principles – a prescription that would later become influential within and outside the United States (Burgin, 2012).

Considerable complexity and uncertainty were nonetheless visible in postwar social science. Economists Alexander Gerschenkron and Albert O. Hirschman developed more sophisticated theories of economic development than the modernizationists' linear model. The leading social science theories of the postwar decades modeled functionalist, cybernetic, and equilibrium systems that expressed the desire for stability as well as the sense of progress achieved. In the work of David Riesman and studies of the 'authoritarian personality' that drew on the personnel and ideas of the Frankfurt school, social scientists found a 'soft' totalitarianism of conformism in the United States parallel to the 'hard' totalitarianism of Nazi Germany and the Soviet Union, although these darker fears did not close off the possibility of progress.

As part of its international leadership role, America worked to export its models of social science theory and research. In Europe, American influence peaked by 1970 as native traditions revived and new theorists analyzed the possibility of progress with greater circumspection than in the United States. The *Annales* historians disaggregated the flow of historical time and turned their attention to the structure of *la longue durée*. In German sociology, the dehumanizing character of modern society remained a powerful, and sometimes dominant, theme. One of the most hopeful German theorists, Jürgen Habermas blended Marxist traditions with American theories of pragmatism and democracy to project not a utopian future, but a utopian ideal against which modern society might measure its defects (Skinner, 1985).

The idea of progress and its drawbacks also played a conspicuous role in the development of the social sciences in the non-Western world. As an arm of secular, Western-style development since the nineteenth century, the social sciences had been a major site of debate over whether or how far to follow Western models of economic growth or revive traditional cultures. After World War II, the developing world also served as a major source of critical revision of Western conceptions of progress as modernization: Latin American economists recast modernization as economic dependency; Japanese social theorists linked the country's rapid economic growth to its blending of capitalist forms and traditional feudal culture. Proliferating formulations of modernity redefined tradition and modernity as mutually transformative rather than diametrically opposed processes (Gaonkar, 2001).

Progress and Postmodernity, 1970–2010

Since the 1970s, long-standing discontents with modernity and the global reach of developmental processes have opened the way for a variety of conflicting discourses on progress. The critique of the positivist conception of scientific progress by Thomas Kuhn's *The Structure of Scientific Revolutions*, 1962, launched the most consequential challenge for the social sciences. Although Kuhn argued that his work did not undermine the rationality of science nor destroy the idea of scientific progress, it did radically remove science from positivism's universalistic narrative of the cumulative, progressive discovery

of truth and resituate it in a social historical world of shifting contexts and revolutionary change (Skinner, 1985). Kuhn's work presented the social sciences with a double challenge. He was skeptical that most parts of the social sciences possessed a paradigm – a shared model of scientific practice – and hence qualified as mature sciences. And by historicizing science, he suggested that the positivist premises of mainstream social science were misguided; the often-marginalized interpretive models of social knowledge based on historicist premises could legitimately claim a central place in the social sciences.

Although Kuhn's critique of the positivist conception of scientific progress had roots in a scientific philosophy allied with positivism, it was soon joined to the mounting philosophical criticism of positivism and to the broader attack on the discourse of progress by postmodern theorists (Isaac, 2012; Bernstein, 1985). The most radical postmodern challenge came from the home of the rationalist Enlightenment. Francois Lyotard linked the idea of progress, with its universalist and rationalist premises, to the most oppressive, totalitarian impulses of modern Western society. Michel Foucault held the social sciences and professions responsible for the knowledge/power that disciplined the unruly masses of modern society in the name of enlightened rationality. Animated by pluralistic and libertarian values, this critique gained power from the proliferation of postcolonial nations and by opposition to the increasing reach of Western capitalism into every area of the world. In the postmodern reading, globalization was producing not a single narrative of universal progress, but a pluralistic, hybrid, decentered world of many historical narratives. If, as the term postmodern suggests, this vision does not entirely escape modernity and can itself be read as a liberationist narrative of progress drawn from Romantic rather than Enlightenment sources, it nonetheless called into question the universalist and rationalist premises upon which discussions of progress had been conducted in the social sciences since the eighteenth century (McGowan, 1991).

In those segments of social science identified most closely with mathematics and natural science, like economics, Kuhn and postmodernism have had little influence. The framework of historical progress held strong in economics, where it remained implicit in the economists' assumption of the beneficent operation of the ideal market and explicit in the neoliberal gloss on free market economics. The economists' own ideology of scientific progress also held firm in continued positivist understandings of science and claims to possession of a consensual paradigm (Backhouse, 1997).

Postmodern currents have more powerfully undermined the discourse and ideology of progress in social science disciplines other than economics, where the political conflicts and social movements of the 1960s and 1970s were more keenly felt. As a result, divisions between positivist and historicist/hermeneutic fields within these disciplines multiplied and deepened (Backhouse and Fontaine, 2010). Anthropology was most deeply shaken by the postmodern assertion that an objective Western science of peoples classified as 'others' was impossible and immoral. In sociology, the historical trajectory of progress from traditional to modern society which had guided social theory through the nineteenth and twentieth centuries appeared less relevant to the issues raised by globalization. As sociological theories built on that scaffolding collapsed, sociologists' visions of historical advance shifted to the multiracial, multicultural, multigendered world valued by postmodernists (Calhoun, 2007).

The power of the economics discipline, together with the fall of communism, continued globalization, and the rise of neoliberalism, revived the discourse of progress in the public sphere. In the United States, the narrative of American exceptionalism and the view of globalization as the Americanization of the world returned. Social scientists formulated and debated more complex narratives of universal progress toward the present form of capitalist society, such as Frances Fukuyama's 'end of history' in the Euro-American model of liberal democracy, David Landes' attribution of Western economic growth to its cultural virtues, and Jared Diamond's geographical explanation for the dominance of the modern societies of the Eurasian landmass. Despite the postmodern critique of science and the many fears of science's destructive capacities, the scientific and technological conquest of nature often remained the chief motor and guarantee of progress in these narratives and in the self-conception of the social sciences themselves. Still, the context of fragmentation and critique forced some social scientists to abandon, and others to reconsider, the ability of their disciplines to meet the criteria of scientific progress (Rule, 1997; Smelser, 2005). If the eighteenth-century formulation of historicism launched the discourse of progress and gave the social sciences their charter, the critical historicism of the late twentieth century had called both progress and that charter into question.

This article is a revision of the previous edition article by G. Stricker and K. Somary, volume 18, pp. 12181–12185, © 2001, Elsevier Ltd.

Abstract

Projective techniques is a term that refers to any test or procedure designed to provide information about individuals by allowing them to respond freely to ambiguous stimuli. This article reviews the history of these techniques and the unique insights they provide. Additionally, the article focuses on four of the most frequently used specific projective tests, the Rorschach, the Thematic Apperception Test, projective drawing tests, and sentence completion tests. These tests' administration is reviewed and their psychometric strengths and limitations are listed. Finally, the article concludes by identifying the place of projective methods within the larger sphere of psychological testing.

Projective techniques is a term that encompasses any test or procedure designed to increase insight into individuals by allowing them to respond freely to ambiguous stimuli. The underlying assumption is that, when faced with unstructured or ambiguous stimuli, people will reveal aspects of their personality in their attempt to structure the material. In other words, the vague quality of the stimulus evokes free fantasy play and triggers projection on the part of the subject while simultaneously revealing aspects of psychological functioning in the nature of their responses. Many experts believe that everything said or written in response to a stimulus has dynamic meaning and that people reveal conflicts, anxieties, attitudes, beliefs, and needs in their attempt to structure or complete an incomplete stimulus. Projective techniques tend to have brief, general instructions that, when coupled with ambiguous stimuli, tend to elicit less defensive responses than more structured testing. It should be noted that a concern about conflicts, anxieties, attitudes, beliefs, and needs, and the usual attempts to blend these into a picture of a person, is most closely associated with one approach to personality, the psychoanalytic approach. A preference for psychodynamic theory is not required in order to use projective techniques, but it is frequently found. Perhaps this is because one of the hallmarks of the psychoanalytic approach is the prominent role assigned to unconscious processes, and projective techniques are designed with the intention, satisfied or not, of eliciting unconscious material.

Historical Overview

Historically, the turn of the twentieth century was a time when psychological testing was applied predominantly for the study of intelligence. The trend was toward finding data or norms descriptive of groups of people (nomothetic data). At this time, personality measures tended to examine only a single trait at a time (e.g., introversion/extroversion, flexibility). The scope began to broaden about two decades later when interest surfaced in tests that yielded specific data about an individual (idiographic data). In the 1920s and 1930s, a variety of projective testing instruments emerged that relied in part or whole on the concept of projection. The notion of projection with these tests gave birth to the progression of projective techniques throughout the rest of the twentieth century and the belief that ambiguous stimuli can be used to gain insight into the dynamics of the respondent. Frank (1939) coined the term 'projective methods' to describe a variety of techniques used by clinicians with ambiguous stimuli that pull for projection. He postulated a projective hypothesis, namely, that the world is structured according to internal needs and external demands, so that the ambiguous external stimuli will elicit structuring based on internal factors. Projective tests varied on the nature of the stimuli and the tasks required; some require association to inkblots (e.g., Rorschach), others completion of incomplete sentence stems (e.g., sentence completion tests), and still others construction either of drawings (e.g., Draw-A-Person (DAP) test) or stories (Thematic Apperception Test (TAT)). The 'Projective Movement' grew tremendously during the 1940s and 1950s, as clinicians moved away from the nomothetic approach to studying their patients toward the more idiographic approach. More recently, because of psychometric considerations, and possibly because of a reduction in the number of clinicians trained in psychodynamic approaches, the use of projective techniques has waned, leaving an open question and considerable controversy over the value of the projective approach.

There is also disagreement about how, or how much, to classify a test as projective. Arguably, the leading modern-day researcher on the Rorschach (Exner, 2003) has argued that only a minority of the variables coded on the test involve the process of projection. More recently, some have argued (Meyer and Kurtz, 2006) that classifying tests as either projective or objective (objective is usually defined as the tests in which there is a limited set of answers to questions and the answers are scored to an objective preexisting key) tends to give rise to misleading connotations. In particular, it may be assumed that the objective tests are more reliable and valid; and projective tests are more subjective, less reliable, and even less valid. Free response and performance-based tests have been suggested as alternative terms to refer to projective tests as these terms do not appear to imply problematic psychometric qualities.

Psychometric Considerations

A psychological test or assessment device is subject to evaluation on standard dimensions and, regardless of how compelling

a rationale may be, must demonstrate that it meets the usual psychometric criteria before it can be considered to be useful. Foremost among these criteria are reliability and validity.

Reliability

Reliability refers to the extent to which a test provides a consistent measure of what it is measuring. If a test lacks reliability, it is akin to using a rubber ruler, providing different measurements each time it is applied, and there is little credence that can be given to any of those measurements. The first approach to the measurement of reliability is internal consistency, which assesses the extent to which every item in a test is measuring the same characteristic. The second approach is through test–retest, the idea that if the construct that is being assessed is stable then a test should come up with a similar score or measure when the test is given on two separate occasions. The third approach is whether there is reliability between different raters of a test. If different individuals are looking at the same sample of behavior that is measured on the test (i.e., an answer to a question, a drawing, or a response to an inkblot), they should be able to code that behavior in a similar fashion.

Although the most projective techniques employ many items, the items often are designed to be responsive to different dimensions, and so, a projective test may often be seen as a collection of disparate single items rather than a collection of redundant items. Unfortunately, in measurement, redundancy is often desirable, and it is well demonstrated that single items are subject to far more unreliability than collections of items, in which errors may cancel each other out. If there are indeed collections of single items, it can be argued that the test really is a collection of tests, each of which measures a single dimension (and therefore requires a separate assessment of reliability and validity). In such a situation, it can be argued that it serves to reduce the reliability of each. Proponents of projective tests would counter that the object being measured is personality, which contains several dimensions, and that the items should converge to produce a clear picture of the multidimensionality of the respondent. On either side of the argument, item consistency is typically not a measure of reliability evaluated for projective tests. More typically, researchers and test developers examine the reliability in terms of the stability of the scores (test–retest) and consistency of coding (interrater reliability). To the degree these measures of reliability are wanting, the validity of the test is negatively impacted.

Validity

Reliability is necessary but not sufficient for a test. An unreliable test cannot be valid, but a reliable test may not necessarily be valid. Validity is an assessment of the extent to which a test measures what it is intended to measure. This leads to a very interesting problem in assessing the validity of projective techniques. Most projective techniques purport to measure many different aspects of the person, and it is necessary to indicate the validity of every inference that a test draws. Thus, rather than asking, for example, whether the Rorschach is valid, it is necessary to ask, for each inference drawn from the Rorschach, whether or not that inference is valid. One statistical estimate cannot represent the validity of the test, and the general question cannot be answered (Stricker and Gold, 1999).

It is not unusual for a research project to compare the validity of projective techniques with more objective, self-report, and measures of personality (e.g., McClelland et al., 1989). The usual finding of such studies is that the two approaches do not correlate with each other. Some people have interpreted this as indicating a failure in the validity of the projective approach, a conclusion that assumes the validity of objective tests (Lilienfeld et al., 2000). Others (e.g., Hiller et al., 1999) have determined that this lack of correspondence indicates that each approach is valid, but that they are measuring different aspects of the person. This view suggests that objective tests are superior at measuring objective criteria, such as behavior, whereas projective approaches are superior at measuring more covert, unconscious aspects of the person (Hiller et al., 1999). This interpretation is consistent with the theoretical position that usually underlies each of the approaches to measurement.

It is also reasonable to ask whether the incorporation of a projective approach to a test battery adds anything to the process of assessment (incremental validity). If the conclusion about measuring different aspects of the person is accepted, then projective approaches do contribute incremental validity insofar as the assessor is interested in less overt aspects of the respondent. Given the length of time necessary for the administration and interpretation of projective techniques, the question of cost-effectiveness also can be raised. The answer to this question probably is dependent on the individual circumstance. It should be clear, however, that validity, incremental validity, and cost-effectiveness are separate questions, and the answer to one does not determine the answer to the others. In the review of the most commonly used projective tests, along with a description of the tests and their administration, both their reliability and validity will be discussed.

Most Frequently Used Projective Tests

Rorschach

The Rorschach test or, as it is sometimes referred to by the public, the inkblot test was published in 1921 by Hermann Rorschach (1921/1942). The use of inkblots was not a new concept in the 1920s. In fact, a popular game among children at the time was Blotto, in which children made or bought premade inkblots and gave interpretations to the blots. Rorschach's clinical interest in the use of blots was sparked in 1911, while working with Eugen Bleuler, his professor and supervisor. Bleuler coined the term schizophrenia and investigated ways to differentiate schizophrenia from other forms of psychosis. Rorschach happened to observe in his work with patients suffering from schizophrenia that they tended to respond differently in Blotto than patients with other forms of psychosis or dementia. He decided to study this phenomenon more systematically and by 1921 had administered the test often enough to believe in its usefulness as a diagnostic aid in identifying schizophrenia and published his findings in a monograph (Rorschach, 1921/1942). In the monograph, in addition to the results concerning schizophrenia, he noted

that certain kinds of responses were consistent with certain personality traits or styles. The monograph included a set of 10 inkblots and described the administration and the initial coding system. Rorschach died in 1922, but his successors saw the potential of his tool as an idiographic, projective measure and worked over the next two decades to develop the scoring system for responses to the inkblots. Although other inkblot sets have been developed (e.g., Holtzman Inkblot Test; Holtzman et al., 1961), Rorschach's set of inkblots are the most widely used and studied.

Samuel Beck was a psychology graduate student who attempted, shortly after Rorschach's death, to do a standardization study on the Rorschach as a dissertation topic. He began his work at the Institute for Child Guidance in New York and later took positions at both Boston Psychopathic Hospital and Harvard Medical School. Over the years, he gained extensive experience with the use of the inkblots and became acutely aware of the need for more intensive work toward standardization (Beck, 1950).

Around the same time, Bruno Klopfer came to Zürich to work as a technician at the Zürich Psychotechnic Institute where Rorschach inkblots were routinely used in the screening of candidates for employment positions. After working there for several years, he immigrated to the United States in 1934 and began working at Columbia University. The psychology graduate students at Columbia, who were frustrated by the lack of formal training available in the use of inkblots, were eager to have him share his experience with them. Klopfer began giving informal seminars to students and, in his work with these students, perceived the need to develop new scoring codes beyond those articulated by Rorschach. Thus, by 1936, Klopfer was working hard to expand the existing coding system (Klopfer et al., 1954).

At the same time, Beck was busy writing papers that criticized the development of new scoring systems for their lack of empirical soundness. He was specifically critical of Klopfer's attempts to expand beyond Rorschach's published system. Over the next 20 years, the arguments continued and both Beck and Klopfer developed different scoring systems. Despite this controversy over scoring, the method of using the Rorschach continued to burgeon. By 1957, five very different scoring systems had emerged.

John Exner conducted a comprehensive review of the five scoring systems in what was supposed to be a journal article, but after several years ended up as a book (Exner, 1969). He found that the administration rules varied across the systems, each collected data differently, and the coding varied across the different systems. Even when the codes included Rorschach's original categories, they were defined differently so that the codes were not equivalent. In the end, he concluded that there were five uniquely different Rorschach tests that used a common set of inkblots. In 1968, he founded the Rorschach Research Foundation to answer which system had the best empirical foundation and which system had the greatest clinical utility. In surveys of clinicians between 1968 and 1972, he found that most clinicians were scoring the tests in a haphazard manner. Many did not score it at all, and those who did tended to use features of different scoring systems. Only a small minority used one system to score an entire test. Exner concluded that he needed to develop a system that integrated features of the available scoring systems that had a strong empirical foundation. In addition to a reliable system with good validity, Exner wanted a system that was not wedded to any single personality theory. Based on a large pool of Rorschach protocols, Exner articulated a standard administration and scoring of the test. He drew on the five existing systems to develop what he labeled as the Comprehensive System. Variables were only included if they could be reliably scored, and the system continued to be reviewed and revised from its first appearance in 1974 to the latest edition (Exner, 2003). Although at one time, many clinicians treated the Rorschach purely as a projective device and simply interpreted the content of the responses according to their understanding of personality with the publication of the Comprehensive System and a sizable body of research supporting its use, the use of the Comprehensive System has become widespread and the accepted standard for interpretation.

Starting in the mid-1990s and continuing for several years (Grove et al., 2002; Wood et al., 1996), a number of criticisms were leveled against the Rorschach and the Comprehensive System. Among the criticisms were questions raised about whether the Comprehensive System's norms overpathologized individuals as well as about the reliability and validity of a number of variables in the Comprehensive System. These criticisms fueled a debate in both, the professional and public literature, about the use of the Rorschach. Many of the criticisms were addressed (e.g., Meyer and Archer, 2001; Society for Personality Assessment, 2005); however, there still remained concerns about the adequacy of the Comprehensive Systems norms (Shaffer et al., 2007) and questions about the validity of some of the variables (Mihura et al., 2012). These concerns, combined with Exner's death in 2006 and the resulting inability to use the Comprehensive System title, led to the development of the Rorschach Performance Assessment System (R-PAS; Meyer et al., 2011). The R-PAS is based on the Comprehensive System and four of its five authors were part of Exner's research group. The R-PAS slightly modified administration to optimize the number of responses, eliminated some variables that either had poor reliability or questionable validity, based interpretations on norms developed from 13 countries, and plotted variables using standard scoring (i.e., t-scaling) to aid interpretation. It holds promise to further solidify the Rorschach's reliability and validity. Initial results indicate good to excellent interrater reliability with the scoring of the R-PAS (Viglione et al., 2012) and good support for some of the composite variables included in the R-PAS (see Meyer and Eblin, 2012, for an overview of the changes and the data supporting the R-PAS variables).

Thematic Apperception Test

In 1935, Christiana Morgan and Henry Murray introduced the Thematic Apperception Test (Murray, 1943), a series of provocative pictures used to explore the respondent's dynamics. The stimuli are more highly structured than inkblots and respondents are required to give more meaningfully organized verbal responses. Respondents are asked to describe the scene in the picture, the apparent emotional content and thoughts of the people involved, what

led up to the scene, and what the outcome will be. There are 31 cards, with some cards designed to be given to all respondents and others to be used with just males or females, or just with adults or children. The original instructions were to have respondents provide stories to a set of 10 cards, and then a week later respond to a second, different set of 10 cards. In actual practice, clinicians vary on which cards and how many are administered, and rarely is the test administered in a second session. This test was developed on the premise, shared by other projective techniques, that people reveal something of their own personality (i.e., their motivational and emotional condition), as well as their cognitive structure, when ascribing thoughts and feelings to ambiguously drawn characters. Other sets of pictures have been developed as stimuli for telling stories, including a set that has animals engaged in human activity for use with children (Children's Apperception Test; Bellak and Abrams, 1997), and a set of photographs with adolescents confronting developmental challenges (Tasks of Emotional Development; Cohen and Weil, 1975). In response to concerns that the TAT oversamples certain issues (e.g., dysphoria) and the lack of ethnic and racial diversity in the drawings' characters, the tell-me-a-story (TEMAS) (Malgady et al., 1984) was developed. However, in spite of the many sets of pictures that have been developed for using the apperceptive approach, the TAT remains the most widely used.

A number of different scoring systems have been developed, but perhaps the most popular scoring method for this test was devised by David McClelland (McClelland et al., 1953). McClelland's work was devoted to measuring achievement motivation and he scored the TAT responses across seven dimensions: (1) stated need for achievement (someone in the story expresses a desire to achieve a goal); (2) instrumental activity (whether the outcome of the instrumental activity is successful, doubtful, or unsuccessful); (3) anticipatory goal status (whether the person in the story anticipates achieving the goal or being frustrated by it); (4) obstacles or blocks (whether the goal in the story is blocked by an obstacle); (5) nurturant press (whether there are nurturing forces aiding the characters in goal achievement); (6) affective states (emotions present associated with achieving or being frustrated by the goal); and (7) achievement themes (when achievement imagery is the focus of the story). Using McClelland's scoring criteria, researchers have been able to achieve a high level of interrater reliability and have been able to show significant correlations between the test scores as predicted indicators of achievement (Vane, 1981). However, the validity has been found to be affected by story length (i.e., poorer validity with individuals giving brief, unelaborated stories). Other scoring systems measuring such personality characteristics and coping methods have shown similar results with very good reliability and results supportive of the test's validity (Hibbard and Porcerelli, 1998; Westen et al., 1990; also see Cramer, 1999, for an overview of other scoring systems and their reliability and validity). However, most clinicians do not use formal scoring systems to interpret the TAT but instead simply read the responses, look for common themes, treat the stories as psychologically meaningful communications, and consider them as projective tools for understanding the patient's underlying conflicts and needs. The use of this intuitive method, along with the variability across clinicians in the cards administered, likely leaves the test's reliability and validity in actual practice much lower than what has been achieved in the published research.

Projective Drawings

In 1949, Karen Machover described the figure drawings by respondents that clinicians could use to identify personality dynamics. In her DAP test, respondents are asked to draw a full person (gender not specified ahead of time), and then to draw a person of the opposite sex of the first drawing. They are then asked to make up stories for each drawing. The absolute and relative size of the persons are examined as well as details such as the position on the page, the quality of the lines, the sequence of parts drawn, the stance, position of the arms, and grounding effects. A similar constructive projective test, the House–Tree–Person test, was developed at the same time by John Buck (1948). There have been a number of variations to these original constructive tests (e.g., Draw-A-Family, Kinetic Family Drawing, Draw-A-Person in the Rain).

The manuals describing the administration, scoring, and interpretation of these tests varies from fairly minimal with little psychometric information (e.g., Buck, 1948) to fairly comprehensive with detailed information on scoring and reliability (e.g., Draw a Person: Screening Procedure for Emotional Disturbance; DAP:SPED; Naglieri et al., 1991). There are three different methods that clinicians have used to interpret the drawings. The first is the use by clinicians of their global impressions and associations to the drawings to develop hypotheses about the artist's self-perception, motor expression, anxieties, or needs. The second interpretation method is to link specific characteristics of the drawing with particular aspects of the artist's personality or diagnosis (e.g., small figures are associated with low self-esteem). A number of authors (e.g., Buck, 1992; Burns, 1987) have produced glossaries that provide interpretations for these specific signs. The third method does not link specific signs with a specific interpretation but rather focuses on the frequency of indicators of pathology in the renderings. This method originated with Elizabeth Koppitz (1968), and the DAP:SPED is a commercially produced example of this method. The interrater reliability of the global impressions method has generally been low and the ability to identify pathology poor (Kahill, 1984). This has been explained by one of the proponents (Hammer, 1997) of this method as due to the interpretation being more "an Art than a Science…half of the psychologists are adept at this art, and about half are not" (p. 377). The interrater reliability of the specific signs approach has been variable depending on the level of training of the raters (Kahill, 1984), but the evidence to support the validity of the interpretations has generally been poor (Kahill, 1984; Swenson, 1968). Both the test–retest and interrater reliability are good for the overall ratings method such as found in the DAP:SPED (Naglieri et al., 1991), and such methods have been able to successfully differentiate emotionally disturbed children from nondisturbed children (Matto, 2002; McNeish and Naglieri, 1993; Naglieri and Pfeiffer, 1992). However, it is not clear that most clinicians use the overall rating method for interpretation, and even with the

use of that method there are concerns about the strength of the conclusions and their value over other tests (Lally, 2001).

Sentence Completion Tests

Another type of projective test is sentence completion tests where respondents are asked, orally or in writing, to complete incomplete sentence stems (e.g., What worries me…; Women…; My mother…). Their origin as a projective test is derived from Carl Jung's use of the word association test, where individuals were given a word and instructed to reply with the first word that they can think of. These word associations were supposed to provide insight into individuals' unconscious ideas and motivations (Jung, 1910). The use of sentence stems was seen as an improvement over just the single word, and starting in the 1930s there have been a number of standardized written sentence completion tests developed. The most widely used (Holaday et al., 2000) of these standardized tests is the Rotter incomplete sentence blank (RISB; Rotter and Rafferty, 1950; Rotter et al., 1992). It has 40 sentence stems that can be self- or orally administered to high school students and adults, and is designed to measure both adjustment and maladjustment. The manual (Rotter et al., 1992) provides an objective scoring system and data indicating acceptable short-term test–retest reliability (but poorer long-term – 6 months to 3 years – test–retest reliability) and good interrater reliability. Using the formal scoring system, the RISB has shown the ability to differentiate maladjusted versus well-adjusted individuals. However, as with the TAT and projective drawings, most examiners (Holaday et al., 2000) appear to use their intuitive clinical judgment to interpret the test rather than a formal scoring system. The reliability and validity of such an approach is unknown. As with the TAT and other apperceptive measures, the value of the task often is dependent on the particular set of items that is employed, and the more closely the items approximate the target being studied, the more valuable the responses can be shown to be (Moretti and Rossini, 2003).

Concluding Comments

It can be concluded, with some certainty, that the original promise of the projective hypothesis (Frank, 1939) has not been sustained, and that there are many limitations on the conclusions that can be drawn from the responses to ambiguous stimuli, especially when psychologists' interpretations are guided by just their associations. However, there is evidence that such stimuli can produce valid inferences, and inferences that cannot be drawn from other approaches to measurement. Traditionally, the inferences drawn from projective tests have been seen as dependent on the theoretical approach and goals of the examiner, whose skillfulness and clinical acumen were important variables in considering the utility of the conclusions drawn from projective methods (e.g., Hammer, 1997). Although such an approach may be valid for particular individuals, it does lend itself to ready verification for the individual and does not allow the test to demonstrate psychometric capabilities. However, projective tests are not limited to solely being interpreted by clinicians' intuition. Because projective techniques do show the promise of providing valid information that is different than that produced by objective measures, it is worth pursuing methods of interpreting these tests that have good reliability and validity so that clinicians are able to gain a more complete understanding of the individuals they assess.

Abstract

This article summarizes the existing empirical findings in the economics literature on promotions in hierarchies. First, the basic facts concerning promotion are listed. Second, the promotion outcomes, focusing on wages, health and happiness, and promotion determinants are discussed. Last, the prominent theories of promotions and the relevant empirical evidence are summarized.

The typical organizational structure of the firm is hierarchical with a diminishing number of positions at higher levels. Most positions in large organizations are filled through promotion rather than hiring from outside the firm. Although outside hiring is conducted at all levels of the hierarchy in large US corporations, over 75% of the executives in the top four reporting levels were promoted into their positions and spent the majority of their working lives within their current firm (Bognanno, 2001). The pay structure in firm hierarchies is convex, exhibiting increasing interrank pay differences. An employee's advancement within the firm is referred to as a promotion. The predominant use of internal promotion to fill vacant positions in the hierarchy and the convexity of the pay structure serve to create strong promotion incentives for workers within the firm. This article first summarizes the empirical findings on promotion outcomes and determinants, focusing on wages, health and happiness and then presents the prominent theories of promotions and discusses the relevant empirical evidence. (For a general review of the personnel economics literature see Lazear and Oyer (2012). For a comprehensive review of the theory and evidence in internal labor markets see Waldman (2012).)

The notion of employee advancement is broad enough for promotion to be defined in different ways. Advancement in responsibilities, reporting level, pay grade or job title all constitute a promotion in some sense. However, the magnitude of the pay consequences and the frequency of the event will differ with the definition. Large firms tend to have more job titles than pay grades and more pay grades than reporting levels. It is possible for one of these aspects to change without a corresponding change in the others. While promotions have been defined in different ways in the literature, a widely used definition is a job change accompanied by upward movement in the hierarchy or in pay.

Annually in US corporate hierarchies, with promotions defined as a job change accompanied by a higher pay grade, roughly 90% of upper level executives are stationary, 9% are promoted or move laterally, and less than 1% suffer demotion. At higher levels in the firm hierarchy, the rate of promotion decreases, while the rewards to promotion increase. The rate of growth in pay also increases at higher levels. Not surprisingly, changes in pay are most favorable for the promoted and least favorable for the demoted. The full financial rewards of a promotion are not realized immediately; in the years subsequent to a promotion, pay increases remain elevated but dissipate with time. (Belzil and Bognanno (2008) find the rate of pay growth to be higher at more senior levels in the firm. The annual percentages of executives promoted, remaining in position and demoted are taken from this article. Their data support the findings summarized in the paragraph. Evidence of higher rates of promotion in lower hierarchical levels was noted in Baker et al. (1994b) and Belzil and Bognanno (2008).)

Promotion Outcomes

Promotion has been established as important to wage growth for employees in organizations. Through the analysis of personnel records from individual firms, both Lazear (1992) and Baker, Gibbs and Holmstrom (henceforth BGH (1994a,b)) demonstrated the importance of promotion on within-firm wage growth. Lazear (1992) used 13 years of personal records to study the influence of job assignment on wages and turnover for full-time workers at a large durable-goods manufacturer. Job change was linked to wage growth. Workers remaining more than 7 years in the same job suffered declining real wages. Most of the variation in pay was found to exist between jobs and not within jobs. BGH (1994a,b) used 20 years of personnel records in a detailed examination of the internal labor market of a large firm. Promotion was necessary to wage growth in the firm, as real pay fell with increasing position tenure. Hierarchical level in the firm alone explained about 70% of the variance in pay (BGH, 1994b). Controlling for age and tenure, Bognanno (2001) finds that increasing time in a position reduces the pay of all executives except Chief Executive Officers (CEOs) in an analysis of an 8-year panel consisting of hundreds of the largest US firms. Age, education, and level in the firm explained 43% of the variation in pay. With the addition of controls for the worker's firm tenure, job tenure, whether the executive was externally hired into the position and firm fixed effects, 69% of the variation in pay was explained.

Interestingly, research focusing on the nonmonetary aspects of promotion indicates that promotion may be a mixed blessing. Higher ranking positions are associated with higher levels of responsibility and stress. Consequently, the effect of a promotion on a worker's overall wellbeing might be negative. Unfortunately, the overall effect of a promotion is not easy to assess in a simple cross-section of workers. Workers in lower ranked positions are potentially different from workers in higher positions in ways other than level. The innate

characteristics that contribute to high performance and promotion may in themselves be related to stress levels, independent of the level of the job.

A recent paper (Johnston and Lee, 2013) addresses this problem by employing the Household, Income and Labor Dynamics in Australia survey to assess how a promotion affects a worker's overall wellbeing. On the positive side, they find that a promotion produces increased job satisfaction in the short run (approximately 3 years) and increased income permanently. However, while happiness and physical health outcomes remain unchanged, there is a lasting negative effect on mental health and a lasting increase in hours of work. Workers report a significant deterioration in their mental health due to job stress approximately 2 years after a promotion. The authors conclude that promotions do not increase workers' wellbeing and potentially have a negative mental health effect.

Similar findings are reported by Boyce and Oswald (2012) using the British Panel Household Study. They report that promotion leads to a significant deterioration in the psychological wellbeing of the promoted workers. Kosteas (2011) also reports a short term positive effect of promotions on job satisfaction after controlling for wage increases in the NLSY79. Additionally, workers who believed promotion was possible in the near future had higher job satisfaction and lower quit rates, supporting the idea of a beneficial 'anticipation effect.'

Promotion Correlates and Determinants

It is challenging to accurately predict promotions from year to year when the large majority of executives are stationary. However, promoted executives differ on average in some respects from those not promoted and there are factors that make promotion more likely. In terms of differences between those advancing and those not, promoted executives tend to earn more than others in their reporting level prior to promotion and the percentage of promoted executives with above average earnings prior to promotion increases with level (Bognanno, 2001). Additionally, promoted executives tend to receive large pay raises prior to promotion (BGH, 1994a; Belzil et al., 2012; Gibbs, 1995; Dohmen, 2004). In the year prior to a change in the CEO, the highest paid non-CEO in the firm is selected as the new CEO about 80% of the time (Bognanno, 2001). Belzil, Bognanno and Poinas (henceforth BBP, 2012) found that promoted executives tend to be younger, more educated, and have less firm tenure than others in their job who were not promoted. BGH (1994a,b) also find education positively correlated with promotion probabilities. A positive correlation between the employee's performance ratings in the firm and the probability of promotion has also been found in the literature. (See Medoff and Abraham (1980), Dohmen (2004), and DeVaro and Waldman (2012).)

Several studies have reported evidence consistent with the notion of a 'fast track.' (See Gibbs and Hendricks (2004) and references therein.) The idea is that some executives exhibit a faster rate of promotion and appear to be on a 'fast track.' The finding of a positive correlation between an executive's promotion in 1 year and promotion in the next, consistent with 'fast tracks,' appears in BBP (2012). Promoted executives in their data have about a 75% greater likelihood of promotion in the year following a promotion than nonmovers and about a 70% greater likelihood 2 years later. Additionally, prior to promotion, the soon-to-be promoted executives were younger and had below average position tenure in comparison to nonmovers in the same job and firm.

A careful model of the determinants of promotion cannot use pre-promotion relative wage position or wage growth as exogenous variables because the process of wage determination and promotion is arguably closely linked. BBP (2012) consider a model of promotion probability that conditions on unobservable individual heterogeneity, allows for an endogenous initial condition, and considers the explanatory power of exogenous individual and firm characteristics. They find that the most influential determinant of promotion is unobserved individual heterogeneity. Persistent unobserved individual heterogeneity explains 70% of the variation in promotion probabilities. This factor could represent executive ability, of which there was no measure in the data.

Promotion determinants of lesser importance in BBP (2012) are past career advancement speed, human capital (age and education), firm variables (profits, sales and size), tenure and newcomer status at the firm, and reporting level in the firm. Education and firm tenure have a weak positive influence on promotion probabilities. Age, newcomer status and level have a negative effect. Age, education, tenure, newcomer status in the firm and unemployment upon hire combined account for only 8.3% of the variation in promotion probabilities. Firm variables are even less influential. Sales, profits and employment levels accounted for only 3% of the variation in promotion probabilities. The contemporaneous national unemployment rate had a very slight dampening effect on promotion, while the unemployment rate upon hire had no effect.

BBP (2012) found promotion probabilities to differ by functional area. Marketing services, management areas, and manufacturing appear to have an advantage in promotion. The three weakest functional areas for promotion were employee relations, legal and management information systems. The functional areas account for 5.4% of the variation in promotion probabilities.

Theories and Empirical Support

The Tournament Theory of Promotions

The application of tournament theory to promotion in hierarchies is appealing in part because the theory provides an explanation for the increasing interrank pay spreads observed in organizations. As such, it provides a rationale for high levels of CEO pay, a topic that receives considerable attention. It is also consistent with the high rate of internal promotions in organizations to fill position vacancies and with the diminishing number of positions at higher ranks in the organization.

The tournament model (Lazear and Rosen, 1981; Rosen, 1986) views promotions as a 'prize' for which workers compete – promotions serve as an instrument to align the incentives of the workers with the interests of the employer. In the model, managers are in a competition to climb a hierarchical ladder; the pay increase associated with

climbing to the next rung, combined with uncertainty over who will be promoted, induces them to provide effort.

Consider a firm with many workers. Worker output is a function of effort and luck. Output is observable to the owner but effort is not. To induce the workers to exert effort, the owner promises a prize in the form of a bonus (promotion) to the workers who produce the most output. At the end of the period, the best or a top share of workers are promoted to the next level and receive the accompanying pay increase. Providing an incentive in the form of such a rank-order tournament, in which the workers are rewarded based on their relative performance, has three distinct advantages over piece-rate contracts (payments based on the amount of output produced). First, it might be easier to evaluate the relative performance of workers than measure their absolute performance in certain settings. Second, in the tournament model, the owner has no incentive to be dishonest about the level of output workers produced; the owner is committed to promoting the best performing workers, independent of their level of output. Third, if worker output is subject to a common random shock that impacts the output of all workers, paying them based on absolute output (a piece-rate) exposes workers to risk to which they may be averse. The rank order comparisons used to allocate prizes in tournaments filter out this common shock.

There are tradeoffs faced when operating a promotion tournament if the objective includes both selecting the best person for a position and maximizing the effort exerted when workers are of unequal ability. The greater the difference in ability, the less likely it is that the outcome of the competition will be determined by the level of worker effort and the weaker the promotion incentives become. The firm can counteract this by handicapping the participants to create an even competition and improve the incentives to exert effort but doing so reduces the likelihood that the more able participant will win. The firm cannot both select the most able worker and maximize incentives.

Another aspect of the tournament model is that a worker's current pay is not directly tied to current productivity and does not serve as an incentive to the worker receiving the pay. However, it does serve as an incentive to the workers below who are motivated by the prospect of potentially receiving this pay upon promotions in the future. This incentive property of the hierarchical pay structure also implies that the pay raises upon promotion must be large enough to induce the agents to exert effort, i.e., there must be discrete jumps between pay grades. Moreover, the size of the pay increase is inversely related to the probability of a promotion. It is more difficult to be promoted to the level of a CEO than to be promoted from shift worker to supervisor of a small group of workers, so the promotion to CEO should carry a much larger pay increase. As well, the pay increase upon promotion to CEO is larger because that is that last promotion one can receive. Promotion at lower levels carries the immediate reward and the option value of remaining in the tournament and in contention for subsequent promotions.

The widespread use of tournaments is noted in Baker et al. (1988) in a study summarizing the empirical evidence on the firm's internal incentive structure. It reports the "overwhelming use of promotion-based incentive systems" rather than pay-for-performance systems, especially in settings where performance evaluation is subjective.

Moreover, there is a substantial literature testing individual predictions of the tournament theory. First, as discussed above, the pay increase associated with a promotion should be positively related to the number of workers competing for that promotion. This is supported by Leonard (1990), who finds that pay differentials are higher toward the top of the hierarchy and that pay increases are greater if the promotion rate is lower. All employing panel data including more than 200 firms, Main et al. (1993), Bognanno (2001), and Eriksson (1999) find support for the tournament theory hypothesis that the reward for promotion to CEO should increase with the number of competitors for the position.

Also supportive of tournament theory, DeVaro (2006) presents evidence from the Multi-City Study of Urban Inequality, a cross-sectional survey of 3000 establishments in four metropolitan between 1992 and 1995, suggesting that promotions are determined by workers' relative performance. He structurally estimates a model of promotion tournaments in which worker performance, the wage spread, and promotions are endogenous. The results support the tournament model in that worker effort is increasing in the wage spread and decreasing in the random component (luck) of promotion. Firms, in turn, increase the wage spread in the presence of a large random component to maintain incentives.

As the filling of vacant positions via promotion is pervasive and promotions bring financial rewards, promotion incentives are created within firms. However, there is still the question of whether firms intentionally manage them at the level of the individual. Some findings in the literature conflict with the notion that firms manage promotion incentives in accord with tournament theory. Gibbs (1995) found that those waiting longer for promotion received a smaller pay raise from promotion. Workers who go long periods without promotion suffer a decrease in the lifetime value of a promotion because they are closer to their retirement age and also have a reduced probability of being promoted at all given they have been passed over previously. Gibbs (1995) found no evidence that the firm altered short-term incentives in response to changes in these promotion incentives.

A similar result is found in Bognanno (2001), where an additional year in the same position prior to a promotion in level reduced the pay increase from the promotion. One explanation of this finding based in the actual practice of compensation administration is that executives who go longer without a promotion are more likely to have risen higher in their pay grade prior to promotion and promotion to the bottom of the next of the next pay grade constitutes a smaller increase for them. Bognanno (2001) documents that, relative to other workers in the same reporting level, promoted workers earn more than average before promotion and less than average afterward.

Asymmetric Learning and Job Assignment

In the basic tournament model described above, positions do not differ, except in pay. Promotions result purely as an incentive device for workers to provide effort. An alternative (or additional) rationale for promotions is provided by

assignment models. Firms are a collection of positions, each fulfilling different tasks and hence requiring different abilities and skills. Over time, the firm and the worker learn about the position that is best suited for the worker, so promotions lead to a better assignment of workers to positions, while the higher pay is intended to retain the worker in the firm. In this class of models, a promotion signifies an improvement in the 'match' between the worker and the job.

A common feature of assignment models is the presence of asymmetric information about the worker's ability. In Waldman (1984), the current employer learns the worker's ability after one period of employment, whereas other employers do not learn the worker's ability and only observe current and past job assignments. This asymmetry creates a strategic element in the current employer's decision of whether or not to promote a worker. A promotion of a high-ability worker improves job sorting and increases output, but also sends a signal to the job market that this worker is of high ability. In order to avoid having the worker poached after a promotion, the current employer must provide a sufficiently large pay increase; wages do not depend on the worker's productivity in the current job assignment, but rather the value of the worker as perceived by outside employers. As a result, the current employer promotes fewer than the socially optimal number of workers.

Asymmetric information about workers' ability can also explain the aforementioned fast tracks. Serial correlation in promotions can arise for two reasons. First, more able workers accumulate the human capital necessary for promotion more quickly and, hence, exhibit a faster rate of promotion at each level of the hierarchy than less able workers. Second, by promoting a worker in the past, the current employer has already signaled that the worker is of high ability. The worker is then already paid accordingly, making subsequent promotions less costly. This, in turn, implies that the employer will choose to strategically delay a promotion for other workers in order to avoid having to adjust the wage rate.

Bernhardt (1995) shows that the signaling effect of promotion has important implications for the probability of promotion for workers of different observed skill levels. As the firm has to pay a worker with high observed skill (e.g., education) more than a worker with low observed skill, the high-skill worker is more likely to be promoted, even if both workers are of equal ability. The resulting wage increase upon promotion is smaller for the more skilled worker, which implies that a worker with low observed skill must be of very high ability in order to be promoted. However, after the initial promotion of the low observed skill worker, the worker's high ability is revealed, which implies that the observed skill level will matter less for future promotions. One implication of this is that the higher a worker is in the hierarchy, the less important observed characteristics become.

One line of empirical research on the assignment model looks for evidence of a promotion signal. It is natural that promotion brings about a pay increase; however, if the pay increase is larger for promotions that reveal more positive information to the labor market about an employee, support for the notion of promotion signaling is found. More information would be revealed when those with less observed skill (e.g., education) are promoted or when younger workers with little labor market history are promoted. Findings on the potential signaling role of promotions appear in DeVaro and Waldman (2012) and Bognanno and Melero (2012).

Using the data from the large US manufacturing firm analyzed by BGH (1994a,b), DeVaro and Waldman (2012) look for evidence in support of two promotion signaling implications that they draw from Bernhardt (1995). Because it less costly to the firm to promote someone who is already thought of as highly able in the external labor market, more educated workers should have an advantage in being promoted over the less educated, performance held constant. As well, the wage increase upon promotion should be greater for those who are promoted among the less educated. They find supportive evidence for both implications. In a more recent article using data from the British Household Panel Survey for the period 1991–2005, Bognanno and Melero (2012) also find support for the implication that those with less education, who are nevertheless promoted, receive larger promotion rewards. Younger workers also receive larger pay increases upon promotion when promotion is defined as the attainment of new managerial responsibilities.

Another line of empirical research on the assignment model focuses specifically on fast tracks. The source of fast tracks has been hypothesized to result from a promotion signaling effect and also simply from the persistent benefit of an executive having higher ability. In an attempt to determine whether in-sample promotions yield an inherent benefit in subsequent promotion, BBP (2012) estimate a model of promotion that conditions on unobserved individual heterogeneity (controlling for persistent unobserved differences in ability). They find no evidence that in-sample promotions increase subsequent promotion probabilities, indicating that promotions do not yield an inherent benefit in subsequent promotion for upper-level management. Hence, the notion of fast tracks resulting from the persistent benefit of being of high ability is supported over the notion that fast tracks result from the signaling effect of promotion. Despite this finding, it may be the case that early career promotions for younger, lower ranking employees have a signaling effect that provides a benefit in subsequent promotions.

Human Capital and Symmetric Learning

An additional facet to the theoretical consideration of promotion is the role of human capital acquisition by the worker. This human capital can be specific to the firm, specific to the task the worker is performing, or general in nature. A promotion can serve as an incentive to accumulate firm-specific human capital. Prendergast (1993) illustrates how a firm can use the prospect of a promotion to a higher paid position to induce the worker to invest in firm-specific human capital. In the absence of a second position, a firm always has the option of reneging on the promise to increase pay if the worker's specific human capital is not verifiable by an outside party and, hence, not contractually enforceable. However, the presence of a higher paying second position, that also produces more output for the firm, aligns worker and firm incentives: the worker has an incentive to accumulate specific human capital in order to be promoted and the firm has an incentive to promote the worker since the new position generates a larger surplus for the firm.

Bayo-Moriones and Ortín-Ángel (2006) use data from interviews at 653 Spanish industrial plants in 1997 and find that use of internal promotion for blue-collar workers is higher at plants in which those workers acquire more specific human capital. However, Sullivan (2010) notes that, after controlling for occupation and industry tenure, tenure with one employer does not lead to significant income gains, suggesting that employer-specific human capital may play a minor role in promotions for most workers. In fact, he finds that the returns to tenure are at the industry level for managers.

A more comprehensive model is presented in Gibbons and Waldman (1999). This model integrates job assignment, symmetric learning and on-the-job human capital accumulation into a unified framework and delivers predictions which are broadly consistent with the empirical evidence in BGH (1994a,b): (1) large wage increases upon promotion, (2) serial correlation in wage increases and fast tracks, (3) frequent real wage decreases, and (4) infrequent use of demotions. These results arise because workers who are promoted quickly are those for whom the employer has revised innate ability upward the most. Higher innate ability causes productivity to rise faster with experience. Thus, an early promotion leads to a large increase in pay, results in large future pay increases, and reduces the time necessary before the next promotion. For other workers, the expected ability is revised downward and, hence, their real wage falls. The worker, however, is not demoted unless the downward revision is very large, making demotions infrequent.

Gibbons and Waldman (2006) extended their model to include schooling and task-specific human capital. This enriched model is able to account for the increased promotion probability for higher educated workers because more educated workers begin their careers with more human capital and continue to accumulate human capital more quickly because schooling is assumed to be positively correlated with the worker's ability to learn on the job. Thus, more educated workers advance more quickly through the job hierarchy. Task-specific human capital produces a so-called cohort effect, in which a cohort that is initially hired at a relatively higher average wage continues to earn a relatively higher average wage many years later. Cohort effects have been found in the empirical literature (see BGH (1994b) and Oreopoulos et al. (2012)).

The theoretical and empirical literature relating to promotion is evolving, resulting in a better understanding of the wage and promotion dynamics with in firms. At the same time that the importance of promotion has been made clear for earnings, new evidence questions whether promotions lead to an increase in the employee's long-term wellbeing.

Propensity Scoring

MH Clark, University of Central Florida, Orlando, FL, USA

Abstract

A propensity score is the conditional probability that a participant will be assigned to a treatment condition given a set of observed covariates. These scores are used as a single, aggregated covariate to make statistical adjustments through matching, weighting, stratifying or covariate adjustments to reduce selection bias in nonrandomized designs. Assuming that propensity scores are computed from all relevant covariates, propensity score adjustments should balance the treatment and control groups in an experiment and provide an unbiased estimate of the treatment effect.

Quasi-Experiments and Selection Bias

Although few would argue that randomized control trials are the most effective designs when making strong, causal inferences, many social and behavioral scientists find that their field experiments do not allow for random assignment to conditions. In such cases, researchers frequently opt for quasi-experiments instead. Quasi-experiments are very similar to randomized experiments except that they lack random assignment to conditions. Assignment to conditions may be based on self-selection, sequential selection, or preexisting groups. While nonrandom assignment may be more realistic or convenient, it also weakens the internal validity of an experiment, making it more difficult to make causal conclusions. According to John Stuart Mill, there are three criteria that establish our ability to make causal conclusions: (1) there is a significant relationship between the cause (independent variable) and effect (dependent variable), (2) the cause precedes the effect, and (3) we can rule out all other causal explanations – that is, the cause really is what is responsible for the treatment effect or change in the dependent variable (as cited by Shadish et al., 2002). In theory, random assignment balances all characteristics of those assigned to each treatment condition. Therefore, when the independent variable is manipulated, the only reasonable causal explanation for a difference in the treatment and control groups is that the effect was caused by the manipulated variable. In the absence of random assignment, we are no longer able to rule out alternate causal explanations for the cause and effect relationship, since it is very likely that other factors may be responsible for the difference between the conditions.

Although well-designed quasi-experiments can avoid many threats to internal validity, they are inherently at risk of selection bias. Selection bias is an imbalance of one or more factors between the experimental and comparison groups that influences the outcome in an experiment. It occurs when the reasons for selection are unknown, such as when participants self-select into a treatment condition for reasons unknown to the experimenter. For example, if alcoholics enroll themselves into a rehabilitative treatment program, they may be systematically different (i.e., more motivated to recover) than those who do not seek treatment. Therefore, the motivation to recover may be what is responsible for their recovery as much as (or instead of) the intervention itself.

Methods for Reducing Selection Bias

Using quasi-experiments does not prevent us from examining causal relationships, but they do limit our confidence when making causal inferences. Therefore, to increase the validity of these claims, we must modify our research designs, analyses, or both. When circumstances allow it, researchers can modify the research design by adding design elements (Shadish et al., 2002). Design elements include observations, comparison groups, and other factors that may or should not be related to the dependent variables. Adding observations, such as pretests, posttests, or follow-up tests, allow researchers to (1) test groups for similarities prior to an intervention, (2) examine long-term effects of a treatment, or (3) if other events coincide with the treatment, we can observe whether dependent variables continue to change with the presence or absence of our treatment or the other events. Adding comparison groups, such as a no-treatment control, placebo, or alternative or abbreviated treatments, can also permit researchers to identify what specific procedures are responsible for a change in outcome. Including a placebo will allow researchers to distinguish whether the true treatment (e.g., an antidepressant pill) is responsible for an improved outcome over the mere belief that one is being treated (e.g., by taking a sugar pill). Similarly, researchers may be able to see which specific components of an intervention are necessary by comparing a full treatment (e.g., diet, exercise, and reduced stress) to a partial treatment program (e.g., diet alone). Finally, researchers may also want to examine how variables other than the dependent variable are affected by the independent variable to see if the independent variable is what is responsible for the change in the dependent variable. If a researcher finds that a variable that correlates with the dependent variables is also affected by the intervention, it improves the likelihood that the treatment is the cause. However, if a variable that is unrelated to the dependent variable (or is not likely to be influenced by the intervention) changes after the intervention, it is possible that the intervention is not responsible for the change in either outcome.

Although modifying designs is more likely to control for selection bias than statistical adjustments, statistically controlling for known covariates that may bias outcomes is a popular alternative. Statistical adjustments are frequently performed after data have been collected or in cases when designs cannot

be altered. However, for statistical adjustments to be effective, researchers must have sufficient data to make these adjustments. Some of the more common methods of statistical adjustments use pretest observations as covariates in an analysis of covariance (ANCOVA) or to create change scores. Therefore, if treatment and control groups are different at pretest, these adjustments can account for these differences when comparing the posttest scores between the groups. Other methods of statistical adjustments include matching, stratification, weighting, and adding covariates to regression models (as opposed to an analysis of variance). These methods, which are described in greater detail below, can accommodate a variety of covariates. Sometimes they are used with a single covariate, such as a pretest; but often they are used with multiple covariates, such as when researchers want to control for several demographic characteristics at once. More recently, researchers combine the simplicity of using a single covariate with the thoroughness of using multiple covariates by using aggregate covariates. An aggregate covariate is a single measure that considers the variance of several variables concurrently. While there are several ways of aggregating measures, the propensity score is one of the most commonly used aggregate covariates.

What Is a Propensity Score?

A propensity score, often notated as $e(x)$, is the conditional probability that a participant would be assigned to a particular study condition based on a set of observed or measured covariates (Rosenbaum and Rubin, 1983). In most cases, they are estimated as the probability that a person would be assigned (or self-select) into the treatment condition, $\mathrm{pr}(z = 1|x)$, where z is the study condition ($z = 1$ specifies the treatment condition) and x is a set of observed covariates. As probabilities, propensity scores range from 0 to 1, where scores above 0.5 predict that a participant will be in the treatment group and those below 0.5 predict that a participant will be in the comparison group. These scores can then be used to equate groups on the observed covariates using statistical adjustment methods commonly used with single covariates, such as matching, stratifying, weighting, or covariate adjustments using ANCOVAs or multiple regressions (Stuart, 2010). In theory, propensity score adjustments (PSAs) should balance the treatment and control groups on all of the observed covariates used to compute the propensity scores, thereby reducing the bias created by nonrandom assignment. Assuming that all variables that influenced the selection into conditions and outcome variables are included as covariates, the adjusted treatment effects should be unbiased (Rosenbaum and Rubin, 1985).

When to Use Propensity Scores

Since their introduction by Rosenbaum and Rubin in 1983, propensity scores have been used to adjust treatment effects in nonrandomized experiments in a variety of social science fields (Casciano and Massey, 2011; Gunter and Daly, 2012; LaFrance et al., 2012), and their use has increased exponentially within the past 30 years (Bai, 2011). Unfortunately, there are adverse effects that come with that increased popularity, namely, that they may be used inappropriately. As with any statistic, there are certain conditions that must be met for the statistical results to be valid. While the continued testing of propensity scores helps to define the appropriate data parameters and sampling conditions (Pan and Bai, in press), it is also important to understand the designs that propensity scores can improve. While propensity score adjustments can be applied to a variety of nonrandomized studies, they were intended to be used with quasi-experiments in which the assignment method is unknown and there are several available covariates that relate to selection. PSAs were created to improve causal inference and internal validity; therefore, they are only appropriate when used with causal studies that have distinct interventions. If the assignment to treatment conditions is based on a known criterion, such as when students are assigned to reading programs based on a pretest of reading proficiency, a regression discontinuity design may be just as effective, and easier to use, than PSAs. It is also important that researchers using PSAs are able to compute propensity scores from several covariates related to both selection into conditions and the dependent variable. If researchers decide to use propensity scores after data have already been collected, they may be limited to a few demographic covariates that do not sufficiently model the selection process. Therefore, it may be preferable to consider the covariates that could influence selection before data are collected so that these can be measured.

Computing Propensity Scores

Selecting Covariates for Propensity Scores

Covariates used to estimate the propensity scores should be related to both the assignment condition (treatment or control) and the dependent variables of the experiment (Austin et al., 2007). Traditional regression adjustments often consider only how covariates relate to the dependent variable. However, if covariates are selected only for their correlations with the outcomes, the resulting propensity scores will not improve the unobserved balance between treatment groups. Since the propensity score is intended to predict selection into conditions, this needs to be the first consideration when selecting covariates. If we are able to account for all factors that influence selection into conditions, the adjusted treatment effects should replicate those from random experiments (Rubin, 2008). While this may be sufficient to achieve balance, some of these covariates may be unnecessary if they are not also related to the outcome. For example, if the treatment group has proportionally more males than the control group, the groups may be unbalanced with respect to biological sex. However, this is only a problem in estimating the treatment effect if sex is correlated with the dependent variable. If so, sex is a nonignorable covariate and should be included as a covariate (Rosenbaum and Rubin, 1983). If not, it may be excluded from the propensity score estimation with little change to the adjusted treatment effects.

However, a bigger concern in selecting covariates is that researchers measure and include enough nonignorable covariates when computing propensity scores. One of the assumptions when using propensity scores is that all nonignorable covariates are included in the analyses. If a covariate, such as

biological sex, is related to selection and the outcome, but is not included in the propensity score estimation, the treatment effects will still be biased. Steiner et al. (2010) found that when covariates were limited to only a few commonly available demographic covariates (i.e., age, ethnicity, sex, and marital status), less than half of the selection bias was removed. Although it was not always the case that adding more covariates reduced more bias, it was important that the most influential covariates (i.e., pretests) were included in the propensity score models. In addition to selecting covariates that are linearly related to conditions and outcomes, it may also be beneficial to include nonlinear covariates or interactions of covariates (Dehejia and Wahba, 1999; Lee et al., 2010).

Although it is important to determine the statistical relationships between each covariate and the assignment condition and outcome, it is not necessary that the covariates are *significantly* related (at $p < 0.05$) to be included in the propensity score model. Even when using common univariate tests (e.g., *t*-tests, chi-squares, odds ratios, Pearson correlations) to assess whether or not there are relationships between individual covariates and assignment condition and outcome, some researchers use a less stringent p value (i.e., $p < 0.20$; Clark and Cundiff, 2011; Diamond and Sekhon, 2013). Other researchers use effect sizes, such as a standardized bias (SB) estimate, to measure the difference between the treatment and control groups for each covariate.

$$\mathrm{SB} = \frac{M_T - M_C}{\sqrt{\frac{s_T^2 + s_C^2}{2}}} \times 100 \qquad [1]$$

where M_T is the mean of the treatment group, M_C is the mean of the control group, s_T^2 is the variance of the treatment group, and s_C^2 is the variance of the control group (Bai, 2013; Rosenbaum and Rubin, 1985). When the covariates are dichotomous, odds ratios can be converted to SB values using a formula similar to Hasselblad and Hedges's (1995):

$$\mathrm{SB} = \frac{\ln\left(OR\right)\sqrt{3}}{\pi} \times 100 \qquad [2]$$

SB values above 5 suggest that the covariates are not balanced between the treatment and control groups and are nonignorable. Unfortunately, just as using hypothesis tests with $p < 0.05$ are probably too liberal for assessing bias, using the above formulae with $\mathrm{SB} > 5$ may be too stringent.

Procedures for Computing Propensity Scores

Logistic regression is the most common statistical procedure for computing propensity scores. In this procedure, all of the selected covariates are concurrently included in a logistic regression model to predict the assignment condition, and the propensity scores are the resulting predicted probabilities for each unit. *Classification* or *regression trees* are used to predict assignment through a sequence of hierarchical, binary splits. Each split is determined by the probability that a participant will select into each condition based on a single covariate. The splitting process continues for each subsequent covariate until a specified number of nodes (or branches) is obtained or until all covariates are included in the model. The resulting binary tree has terminal nodes representing groups of participants who have the same predicted probability for being in the treatment condition (propensity score), even though each node may have estimated the same propensity score from different predictors (Westreich et al., 2010).

Bagging, also known as bootstrap aggregating, averages the results of many classification trees from a series of bootstrapped samples (Lee et al., 2010). In this procedure, cases of participants are randomly sampled (with replacement) from the available data set to estimate propensity scores using the classification tree procedure described above. Cases that are not sampled are used to "estimate the misclassification rate" (Luellen et al., 2005, p. 544). A new classification tree is estimated for each bootstrapped sample, and the resulting trees are aggregated to create a more stable propensity score for each participant. *Boosted modeling* averages multiple propensity score models that were created using different combinations of covariates. Each model is weighted based on its ability to predict the assignment conditions and aggregated to form a single, stable model. Unlike bagging, it uses all available cases from the original sample for each model, and it weights cases based on how difficult they are to classify. Each individual prediction model can be estimated with either logistic regression or classification trees (Lee et al., 2010).

In a study that compared three of these procedures for estimating propensity scores, Luellen et al. (2005) found that logistic regression tended to create propensity scores that were able to reduce bias better than classification trees or bagging. Although propensity scores created through bagging with 100 bootstrapped samples were able to reduce as much bias as those created using a logistic regression, bagging using fewer samples did not yield good propensity scores or consistent results.

Predicting Assignment for Multivalued Treatments

Although propensity scores were originally created to predict the probability that participants would select into one of two conditions, researchers frequently use quasi-experiments that test more than two levels of treatment. In such designs, estimating the propensity score becomes more complicated. When predicting several nominal treatment conditions, researchers can estimate propensity scores by creating separate propensity score models for each possible pair of conditions. Therefore, an experiment with three conditions (i.e., control, medication, and psychotherapy) will have three possible pairs of conditions and will have three different propensity score models. These multiple paired comparisons can be estimated using logistic regression (Falconer et al., 2011; Rubin, 1997) or multinomial or nested logit models (Feng et al., 2011; Imbens, 2000). Although having to account for multiple propensity scores is more analytically cumbersome than accounting for a single covariate, this method maintains a traditional approach to computing propensity scores while accommodating multiple factor levels. Ordinal predictions permit researchers to use an ordinal logistic regression to predict ordered dose-like levels of conditions (i.e., no treatment, partial treatment, full treatment) and results in a single propensity score (Joffe and Rosenbaum, 1999; Park and Russell, 2012). When the independent variable is continuous (i.e., number of cigarettes smoked), Imai and van Dyk (2004)

demonstrated that propensity scores can be created using a linear regression.

Assessing Propensity Score Balance

It is important to keep in mind that the primary goal of the propensity score is not to optimally predict assignment to conditions, but to balance the distributions of covariates over conditions (Rosenbaum and Rubin, 1984). Since the propensity score is an aggregate measure of multiple covariates, it stands to reason that if the propensity scores are balanced between the treatment and control groups, then adjustments using the propensity scores will balance the groups on the individual covariates. Therefore, before using the propensity scores to make statistical adjustments, they should be tested to see whether or not the propensity score distributions are similar for each treatment level. Although there are several statistical tests to determine balance, it is not clear which one is best; therefore, it may be useful to use more than one. The simplest method is to graph propensity score distributions for the treatment and control groups and visually inspect the extent to which they overlap (Bai, 2013; Shadish et al., 2008). For a more objective estimate, a Kolmogorov–Smirnov test can be used to test for a difference between the distributions (Diamond and Sekhon, in press). Finally, Rubin (2001) suggests that propensity scores are balanced if (1) the difference between the treatment and control group means of the propensity scores is less than half a standard deviation, (2) the ratio of the treatment and control group variances of the propensity scores is close to one, and (3) the ratio of the group variances of the residual errors of each covariate predicting the propensity scores is close to one. If the propensity scores are not balanced, rescaling the propensity scores using a logit transformation will normalize the distributions and improve linear modeling (Rubin, 2001).

Adjustments Using Propensity Scores

Matching

Matching identifies and pairs or groups similar cases from experimental and control groups based on the proximity of their propensity scores. Common methods for matching include *exact matching*, in which cases are paired on exactly the same scores; *nearest neighbor* or *greedy matching*, which selects the closest matches first and then progressively farther matches; *caliper matching*, which limits the distance of matches on a specified criterion; and *optimal matching* or *net costmatching*, which finds the smallest cumulative distance from all possible pairs. Although exact matching provides the most precise pairing, it is often unrealistic to use with continuous data unless the range is very small (i.e., age of fourth graders). **Table 1** illustrates the paired results for the last three types of matching.

Although the first few matches made with nearest neighbor matching are very good, the last two matches are poor. Setting a limit to the distance of the match will prevent nearest neighbor matching from having these poor matches. Assuming that the ratios of the variances of the propensity scores in the treatment and control group are close to 1, using a caliper that is four times the pooled standard deviation (s_p) of the propensity scores can remove up to 95% of the selection bias. However, some researchers choose smaller calipers, such as 0.25 s_p. If the pooled standard deviation of the propensity scores is 0.24, then the caliper width is 0.06 (using the second caliper standard). Therefore, the notreatment case can be matched with a control case if the distance between the two propensity scores is farther than 0.06. Since the last two matches using the nearest neighbor method have distances of 0.12 and 0.31, these four cases would not have matches and would be dropped from the analyses that would estimate the treatment effect. Optimal matching does not necessarily drop cases, but arranges pairs in a way so they have the smallest global distance. Although the closest match to the treatment case with PS = 0.63 is a control case with PS = 0.64, this match does not benefit the sample as a whole. Optimal matching considers all possible matches concurrently. Therefore, the summed distances between the propensity scores in the treatment and control groups drop from 0.53 using nearest neighbor matching to 0.51 using optimal matching. Because the poor matches are removed in caliper matching, the total distance between all matched pairs is only 0.1 using the sample data in **Table 1**. Bai (2013) has shown that caliper matching generally tends to reduce bias better than other matching methods. Unfortunately, it drops several cases in both the treatment and control groups, which reduces the sample size and generalizability of the results.

To limit the number of treated participants dropped from the analyses, some researchers recommend having proportionately more participants in the control group to match with those in the treatment group (Rubin and Thomas, 1996;

Table 1 Propensity score matching methods

Unmatched		*Nearest neighbor*		*Caliper*		*Optimal*	
Treatment	*Control*	*Treatment*	*Control*	*Treatment*	*Control*	*Treatment*	*Control*
0.25	0.13	0.63	0.64	0.63	0.64	0.38	0.36
0.38	0.36	0.38	0.36	0.38	0.36	0.41	0.45
0.41	0.45	0.74	0.71	0.74	0.71	0.63	0.58
0.63	0.58	0.41	0.45	0.41	0.45	0.74	0.64
0.74	0.64	0.25	0.13			0.25	0.13
0.89	0.71	0.89	0.58			0.89	0.71

Note: The values in the table are the propensity scores on which participants are matched.

Stuart, 2010). Researchers can also use *index matching* or *ratio matching*, which matches each treatment participant with multiple control participants (Shadish et al., 2002; Stuart, 2010). For example, instead of pairing one person in the treatment group to one person in the control group, we might match each person in the treatment group with three people in the control group. *Full matching* not only permits several control cases to be matched with a single treatment case, but also allows several treated cases to be matched with a single control case. Once treatment and control cases are matched, adjusted treatment effects can be made using a paired samples *t*-test if matching a treatment case to a single control case (Austin, 2008), a generalized estimating equation (GEE) in which the matches are random effects (Clark and Cundiff, 2011), or a McNemar's test if the dependent variable is dichotomous (Falconer et al., 2011).

Stratification

Stratification (also known as subclassification) classifies all of the participants into several categories or strata based on their propensity scores so that each stratum includes participants from the treatment and control groups. Although the number of strata and methods for classifying participants into a specific stratum (i.e., within a certain percentile interval or propensity score interval) can vary (Luellen et al., 2005), Cochran (1968) proposed that five strata of equal sample sizes could account for 90% of the bias from the observed covariates. Once strata are created, there are several ways to compute the adjusted effects. When the dependent variable is continuous, the most common method is to compute a between-subjects analysis, such as an independent measures *t*-test, for each stratum and average effect sizes across strata (Austin and Mamdani, 2006; Shadish et al., 2008). Another method is to use a treatment-by-strata factorial ANOVA that accounts for the propensity scores in the error variance when estimating the main effect for treatment (Clark, in press). If the dependent variable is dichotomous, chi-squares or other contingency table approaches should be used.

Although stratification usually permits the inclusion of all cases, some cells may contain few or no units. Reducing the number of strata or changing the cut-points that define the strata may reduce this problem, but determining ideal cut-points for strata can be difficult (Luellen et al., 2005). While stratification is not as commonly used as matching, the statistical procedures are often less complicated.

Covariate Adjustment

Covariate adjustment uses propensity scores as a covariate in an ANCOVA or a multiple regression and removes bias by accounting for the correlation between the propensity scores and the dependent variable (Rosenbaum and Rubin, 1983; Shadish et al., 2008). Although some studies have indicated that covariate adjustment can be an effective method for removing bias (Austin and Mamdani, 2006; Clark, in press), other researchers do not recommend this method unless covariates or propensity scores are linearly related to the outcome (Rosenbaum, 2001) and variances among covariates are homogeneous (Rubin, 2001). However, in some cases, covariate adjustments using propensity scores may not sufficiently reduce covariate bias even when these conditions are met (Shadish et al., 2008).

Weighting

Weighting attempts to balance treatment and control groups by multiplying observations by the inverse of the propensity score. Two commonly used propensity score weighting estimators are the *inverse probability of treatment weighted* (*IPTW*) *estimator* and the *standard mortality ratio* (*SMR*) *weighted estimator* (Kurth et al., 2006). The IPTW estimator weights observations in both the treatment and control groups by either the inverse of the propensity score or one minus the propensity score. The adjusted mean difference between the treatment and control groups can be found using the following equation by Hirano and Imbens (2001):

$$\widehat{\tau} = \frac{\sum_{i=1}^{N} \frac{r_i z_i}{e(x)_i}}{\sum_{i=1}^{N} \frac{z_i}{e(x)_i}} - \frac{\sum_{i=1}^{N} \frac{r_i(1-z_i)}{1-e(x)_i}}{\sum_{i=1}^{N} \frac{1-z_i}{1-e(x)_i}} \qquad [3]$$

where r_i is the dependent variable, z_i is the treatment condition, and $e(x)_i$ is the propensity score. The treatment effect can then be found by substituting the mean difference in an independent measures *t*-test with this adjusted mean difference.

The SMR weighted estimator only weights the observations for the control group by the odds of the propensity score. The adjusted mean for the control group (M_C) can be found by the equation by McCaffrey et al. (2004):

$$M_C = \frac{\sum_{i=1}^{N} r_i(1-z_i)\left(\frac{e(x)_i}{1-e(x)_i}\right)}{\sum_{i=1}^{N} (1-z_i)\left(\frac{e(x)_i}{1-e(x)_i}\right)} \qquad [4]$$

A single sample *t*-test could be used to determine the difference between this adjusted mean and the unadjusted mean of the treatment group. Although some studies have found that propensity score weighting is effective in reducing bias (Austin, 2010; Kurth et al., 2006), it may not be effective when many propensity scores are very close to one or zero (Rubin, 2001).

Assessing Covariate Balance

Once statistical adjustments are made to the observations, it is important to assess how well the propensity scores balanced the individual covariates between the treatment and control groups. Although univariate tests are commonly used to test for significant differences between groups for individual covariates and omnibus tests, such as Hotelling's T or factorial ANOVAs, have been used to test for imbalance between the covariates as a set, Ho et al. (2007) argue that hypotheses tests are inappropriate, since "balance is a characteristic of the observed sample, not some hypothetical population" (p. 221). Therefore, in lieu of hypotheses tests, SB estimates (eqns [1] and [2]) and measures of bias reduction (Bai, 2013; Shadish et al., 2008) may be used to determine how well PSAs reduced selection bias. If the SB estimate for a given covariate is less than 5 after the PSA, then the adjustment sufficiently

Table 2 Covariate balance before and after propensity score adjustments

Covariate	SB_{unadj}	SB_{adj}	*PBR*
Age	19.50	2.25	88.46%
High School GPA	70.25	12.75	81.85%

balanced the treatment and control groups on that covariate. Even if the SB estimate did not reach this benchmark, we can determine the percent of bias reduction (PBR) from

$$\mathrm{PBR} = \frac{|\mathrm{SB}_{\mathrm{unadj}}| - |\mathrm{SB}_{\mathrm{adj}}|}{|\mathrm{SB}_{\mathrm{unadj}}|} \times 100 \qquad [5]$$

where $\mathrm{SB}_{\mathrm{unadj}}$ is the SB estimate of the covariate before a PSA and $\mathrm{SB}_{\mathrm{adj}}$ is the bias estimate of the covariate after the adjustment (Bai, 2013; Cochran and Rubin, 1973). For example, **Table 2** shows that a PSA was able to reduce the SB for 'Age' from 19.5 to 2.25, which suggests a sufficient reduction in bias. Although 'High School GPA' did not meet the same criterion, the PSA was still able to reduce more than 80% of the observed bias.

Computer Programs That Compute PSAs

There are currently several computer programs and macros that support PSAs. Any statistical package that computes a logistic regression will allow researchers to estimate propensity scores. 'MatchIt' in R (Ho et al., 2011), 'psmatch_multi' in SAS (Fraeman, 2010), 'PS Matching' (Thoemmers, 2012) and Painter's macro (2004) in SPSS, and 'teffects psmatch' and 'psmatch2' in Stata (Leuven and Sianesi, 2003; StataCorp, 2013) all allow researchers to implement propensity matching using a variety of matching methods. While weighting, covariate adjustment and stratifying can also be done in a variety of statistical packages; there are fewer that offer adjustment methods specific to propensity scores (Lanehart et al., 2012; Holmes, 2014).

Limitations of PSAs

Although many studies have shown that PSAs reduce bias as well as or better than traditional covariate adjustments (Shah et al., 2005; Stürmer et al., 2006), other studies have found that traditional or alternative adjustment methods are more effective in reducing bias (Austin, 2010; Kurth et al., 2006; Shadish et al., 2008). This suggests that the specific conditions under which propensity scores are used affects their ability to reduce bias. Statistical adjustment methods, sampling methods, sample sizes, and available covariates all influence the quality of the propensity score and its ability to sufficiently reduce bias (Austin and Mamdani, 2006; Bai, in press; Steiner et al., 2010). Even when propensity scores can sufficiently balance observed covariates, they cannot adjust for hidden bias, which occurs when relevant covariates are not included in the propensity score model. Without including all covariates that contribute to selection bias in the propensity score model, PSAs cannot provide unbiased treatment effects.

Proper and Common Names: Impairments of Anomia

Carlo Semenza, Università di Padova, Padova, Italy; and I.R.C.C.S. Ospedale S. Camillo, Lido di Venezia, Italy

Abstract

Proper names essentially refer to individual entities while common names refer to categories. This fact makes the link proper names have with their reference particularly fragile. As a consequence, processing proper names seems to require special cognitive and neural resources. Neuropsychological dissociations demonstrate that proper names and common names follow functionally and anatomically distinct neural networks. These networks might have been shaped by precise evolutionary demands. Their precise location and working, depending on specific tasks, is still partly unknown. They are, moreover, differently sensitive to focal or generalized brain damage, cognitive changes with age, or lack of organic resources. The sensitivity of proper names to brain damage makes them a useful clinical tool in the early diagnosis of mental deterioration.

Common and proper names have a different type of reference. This is a fundamental distinction that has been shown to impinge on the kind of processing each of the two categories undergoes at the neural level. Its biological value, as it will later be argued, may have been shaped by precise evolutionary demands. Research in neuroscience has thus contributed to the understanding of how proper names are processed in the brain with respect to common names. Past and current philosophical and linguistic theories on the nature of these two lexical categories have directly inspired neuropsychological research, receiving, in turn, empirical support.

The main theoretical idea, originated in philosophy, is that, unlike common names, proper names carry reference, but not (except perhaps in minor role) sense. In other words, they may be considered 'pure referring expressions' (e.g., Mill, 1893; Kripke, 1980) or, as some might prefer (e.g., Searle, 1969), as loci of identifying 'descriptions.' These conclusions are not straightforward, and, indeed they conceal issues that are hotly debated. While aware of this, the neuropsychologist's position is, however, that neuropsychological findings support a common name/proper name distinction in one version or another, the different versions depending on the amount and type of descriptive resources associated with a name. What is sufficient to account for neuropsychological findings is the view that proper names, as opposed to common names, denote individual entities but do not essentially rely on, or rely on only to a limited extent, sets of attributes. Proper names thus essentially refer to individuals (or individual groups) while common names refer to categories. Another useful way of expressing this distinction is that proper names have only 'token' reference while common names carry 'type reference' (Jackendoff, 1983).

As Semenza et al. (1998) observed, a name designating a category applies to a set of attributes that overlap or interact with each other via high-probability connections. In the set of attributes labeled by a proper name, instead, attributes combine together incidentally; they relate to each other only by virtue of belonging to entities that are unique. Moreover, changing features over time does not change the name.

The distinction in the function of common and proper names thus reminds, in some respects, that made between semantic and episodic memory, but with an important difference: the mechanisms distinguishing proper and common names are more peripheral and operate at the interface with the lexical level. Naming individuals with respect to categories does not only imply different connections among defining attributes within semantic memory: it also implies different mechanisms in the activation of the phonological word form. These mechanisms may be understood as types of information-collecting nodes and pointers. In theoretical models proposed in the late 1980s, the main representational and processing differences between proper names and common names have been thus identified in the activation of the phonological form. A review by Cohen and Burke (1993) concluded that, using essentially overlapping concepts, all models emphasized the difference in connectivity serving the token/type distinction. In virtually all these models, only a single connection is envisaged from the individual entity labeled by a proper name and the name. Connections between the components of a concept and a common name are instead multiple and, as a result, are on the whole stronger.

The token/type distinction may not be entirely sufficient to explain all neuropsychological findings, however. Other properties of semantic memory must come into play. The token/type distinction, for example, does not easily explain the case of deictic pronouns (e.g., 'I' or 'you'). Surely these pronouns make token reference. However, no patient with a selective proper name deficit has ever been shown to have problems with deictic pronouns. Clearly, there is an overwhelming difference in word frequency in favor of pronouns. Moreover, 'I' applies to any person pronouncing the word, and this differentiates 'I' from names of persons. The large majority of what are intuitively considered proper names include names of persons, individual animals, specific objects or events, buildings, brands, or geographical places. Some of these subcategories seem to behave in the brain differently from one another. Other referential expressions may pose problems for using the token/type distinction in explaining all phenomena observed in neuropsychology, for example, 'temporal' names: those religious festivities (Easter, Yom Kippur, Ramadan), days, or months. The names of religious festivities have not so far been investigated in patients with deficits relative to proper names and no patient was shown to have problems with the names of days or months. Word frequency may be a factor, but additional properties of temporal names may contribute in keeping keep them apart in the brain from other proper names.

In conclusion, with these provisos, the distinction between individual and general semantics goes a long way in explaining available neuropsychological data.

Neuropsychological Dissociations

In neuropsychology, interesting cases of dissociation were discovered whereby, as a result of a brain lesion, patients were affected by selective anomia for proper names, with normal retrieval of common names. The complementary dissociation, proper name selective sparing, has also been reported.

Anomia for proper names, in general, affects retrieval in all testing conditions and comes in at least four different varieties. The first, and most common, variety, called 'pure proper name anomia' is that originating with a deficit at a postsemantic level. It has been interpreted as a failure to access the name's phonological form from an intact semantic system (e.g., Semenza and Zettin, 1988, 1989; Lucchelli and De Renzi, 1992; Hittmair-Delazer et al., 1994). The phonological form itself seems to be spared in these cases, since the ability to read aloud irregularly spelled proper names is preserved. Two different subtypes have been reported: one concerns all proper names, while the other is limited to the names of persons. It is still unclear whether proper names other than the ones of persons are easier than the latter or rather have particular properties (see above) that may help in circumventing the deficit. Most of these cases are not sensitive to phonemic as well as to semantic cueing, but a combination of both types of cue has been shown to yield some improvement (Semenza and Zettin, 1988). Other patients showing a significant improvement when aided with a phonological cue have been reported (e.g., Lucchelli and De Renzi, 1992; Otsuka et al., 2005).

A second variety of proper name anomia derives from a problem within the semantic system. In this case (e.g., Miceli et al., 2000), information about individual people is selectively lost with respect to information about other entities. In a third variety, instead, the deficit seems to consist in the isolation of information on individual entities from both the general semantic system and the output lexicon (Van der Linden et al., 1995; Semenza et al., 1998). Thus, while some patients cannot retrieve the name but have no problem showing they know everything else about the individual, other less frequently observed patients seem to be selectively impaired in the semantic store containing all the information about that individual, including the corresponding name. In 'isolation' cases, the information was available but could be retrieved by the patient only if given the proper name itself. A last variety is that of 'prosopanomia' (Semenza et al., 2003b). This appears to be a face-specific optic aphasia: while unable to retrieve the names of people looking at their faces, the patient can do so on definition. Unlike in prosopagnosia, the selective inability to recognize faces, there is no trouble in recognizing the face, but like in optic aphasia, the deficit seems to be instead to retrieve enough semantic information from visual stimuli (in this case only from faces) to activate the name.

Anomias for proper names of the first type are also important for their concomitant symptoms. At least in the purest cases, where anomia seems the only reported symptom, careful neuropsychological assessment systematically uncovers a constellation of associated deficits. Semenza and Zettin (1989) thus showed that their proper name anomic could not retrieve a member of an arbitrarily related word pair given the other; likewise, the same patient and similar ones could not retrieve 'token' information arbitrarily connected with other information, such as known phone numbers of people, titles of wordless pieces of music, dates of known events, etc. This finding directly supports theories viewing proper names as pure referring expressions, whose link with the entity they represent is 'arbitrary,' nondescriptive (i.e., not implying attributes), and thus devoid of sense.

Cases of selective sparing of proper names are generally found in otherwise very severely affected patients. These cases are also more complicated than proper name anomias. Severity, on the one hand, has seriously hampered the possibility of testing the patients in the desirable level of detail. Moreover, the conditions in which proper names are selectively spared seem to differ widely from case to case. Unlike in cases of the most common (postsemantic) proper name anomia, which all look rather similar, no single reported case of proper name sparing closely resembles any of the others. The first such case was observed by McKenna and Warrington (1978) and concerned only the names of nations. In the case of Cipolotti et al. (1993), the patient could be tested only in writing, where he could retrieve only names of countries and famous people. Semenza and Sgaramella's (1993) patient could not retrieve any name: the patient's selective preservation of proper names emerged only in the middle of a gibberish jargon, and, more clearly, after phonemic cueing in picture naming. Cipolotti's (2000) patient showed a proper name superiority just for countries, only in oral naming and reading aloud. Schmidt et al. (2004) reported sparing of proper names only in the written condition, in a patient whose articulation was totally impaired. This patient's semantic knowledge about items whose (common) name he could not retrieve was preserved. He never committed paragraphias; these facts led the authors to suggest that the functional deficit could be located in accessing, from an intact semantic level, an intact orthographic lexicon. Unfortunately, this patient's articulation problems prevented assessing the status of his phonological lexicon. In the case described by Lyons et al. (2002), the patient missed not only common nouns but also the correspondent semantic information: in contrast, the patient showed a normal ability to retrieve people's names and the corresponding biographical information. The case of Lyons et al. thus mirrors that of Miceli's et al. (2000). Finally, a selective sparing of proper names was also found by Pavão Martins and Farrajota (2007). Their case, a problem in accessing the phonological form of common names from an intact semantic system mirrors Semenza and Zettin's 'pure proper name anomia' cases (1988; 1989). Importantly, moreover, the same article reports the complementary side of the dissociation: another case of pure proper name anomia, matched for age and education and tested on exactly the same material as the sparing case.

In summary, a double dissociation was found in the production of proper and common names. This double dissociation was found at two different levels, at least. Pavão Martins and Farrajota (2007) showed the dissociation in accessing an intact phonological form from an intact semantic system. Combined together, the cases of Miceli et al. (2000)

and of Lyons et al. (2002) provide a double dissociation at the level of semantic memory. These findings cannot be explained as resulting from a generic difficulty factor, at least as far as the access to phonological form is concerned, since the two patients reported by Pavão Martins and Farrajota (2007) were tested on exactly the same material. Thus, what was difficult for one patient was easy for the other patient and vice versa. These findings support overall the idea that processing proper and common names follows at least partially independent processing pathways in the brain. A theoretical model, based on neuropsychological findings and capitalizing on the separation of individual semantics from general semantic memory and on separate access of this information to the phonological output lexicon, has been proposed by Semenza (2006, 2009). As shown in **Figure 1**, this model accounts for the observed patterns of anomia for proper names.

The Problem of Difficulty

The above-mentioned double dissociation does not, in itself, allow the inference that the two independent tasks are of equal difficulty, however. In fact, the problem of whether the independent pathways used to process proper and common names pose the same burden to the cognitive system is a different problem, independent from the functional and anatomical separateness of the two categories. One pathway, i.e., the proper name pathway, has been traditionally thought to be intrinsically more difficult to use, but an experimental confirmation of this hypothesis has been difficult to obtain (Cohen and Burke, 1993). Pictures of faces (for proper names) and pictures of objects (for common names) are very hard to match for perceptual difficulty. Diary studies, collecting participants' naming failures in a given period of time, may be hampered by the fact that one often hardly notices missing a common name, while missing a proper name may cause serious embarrassment. The best available evidence for proper names being indeed more difficult to process rests mainly on two types of observations. The first concerns the so-called 'baker–baker' paradox: it is easier to learn that a face belongs to a baker than it is to learn that the same face belongs to a Mr Baker (McWeeny et al., 1987). This effect cannot be attributed to differences in the phonological form or frequency of occurrence of occupations versus proper names. Another methodology, repetition of supraspan lists of words, first used in Hittmair-Delazer et al. (1994), shows a significantly weaker priority effect when the list is composed of proper names than when it is composed of common nouns matched to proper names for frequency, length, and phonological complexity. This effect widens with aging, and comes to an extreme with Alzheimer's disease (AD) (Semenza et al., 1996). In young people, a weakening of the priority effect for proper names results from exposure to high altitude (Pelamatti et al., 2003). Overall, these results suggest that the linking of proper names with their reference is more fragile than that of common nouns with their reference and may even require a larger amount of metabolic resources.

Anatomical Differences

The double dissociation shown by clinical cases between naming with common names and naming with proper names suggests that their processing happens in at least partially separate neural structures. Notwithstanding clear neurological dissociations, localizing proper name production with respect

Figure 1 A model of name production distinguishing proper and common names. Proper names anomia derive from disconnections 1–4: (1) 'pure proper name anomia' (anomia in accessing an intact phonological lexicon from an intact individual semantic representations), (2) isolation of individual semantics, (3) loss/degradation of individual semantics, and (4) prosopanomia. In this picture, 'person semantics' stands for individual semantics. The box representing the (output) lexicon distinguishes proper and common names for the sake of clarity, but it does not imply that proper and common names occupy a different space. PN, proper name; CN, common name.

to common names proved to be a hard task. Findings obtained with the classic clinical anatomical correlation method have been further corroborated by lateralized tachistoscopic presentation, event-related potentials, and neuroimaging. The conclusions are not unequivocal, however.

Lesions found to cause selective proper name anomia or proper name sparing, always in the left hemisphere, are, in fact, manifold. They encompass the temporal lobe, the posterotemporal/occipital lobe, the left basal ganglia (including amygdala), and the left thalamus. Available reviews of these cases (whose details may be found in Semenza et al., 1995; Semenza, 1997, 2006, 2009; Yasuda et al., 2000) allow the following conclusions:

1. In proper name anomia, the left temporal lobe is often damaged;
2. Several proper name anomia cases are determined by lesions clearly outside the left temporal lobe (e.g., Semenza and Zettin's, 1988, patient);
3. The left temporal lobe is most often damaged in selective sparing of proper names;
4. At least two cases of selective sparing of proper names follow a lesion in the left temporal pole (LTP).

Findings in single case studies thus contradict a very influential view, originally forwarded by Damasio et al. (1996), in a study combining neuroimaging (positron emission tomography (PET)) with a group study, according to which proper name processing takes place in the LTP. In later studies (Damasio et al., 2004; Tranel, 2006), this view has been considerably moderated. But the same method seemed to confirm the role of the LTP to naming of famous landmarks (Tranel, 2006). The best data in favor of a pivotal role for the LTP come, however, only from group studies in face naming but when proper names are prompted by a definition, the results may be different. Zamarian et al. (2008) thus compared patients with left and right temporal lobe epilepsy on both picture naming and naming of famous people on definition. Left temporal lobe epileptics were worse than right temporal lobe epileptics on naming pictures, but no difference emerged in naming on definition.

The best evidence against the role of the LTP in naming comes, however, from the two cases reported by Pavão Martins and Farrajota (2007). In this study, the LTP was damaged in a patient with sparing of proper names, but undamaged in a second patient who suffered proper name anomia. These two patients had the same age and education and came from the same milieu. Importantly, as mentioned above, they were tested using the same material, thus this double dissociation cannot result from any unbalance between the tests tapping each of the two name categories. Unlike in the case of group studies, in each single case, the dissociation between proper names and common nouns is clearly demonstrated in a series of tasks, in particular those tapping the lexical retrieval level. Such dissociation is not guaranteed in the group study approach. A detailed discussion about the possible role of the LTP in proper name processing can be found in Semenza (2011). The LTP is indeed likely to play an important role (see below), but clinical evidence accumulated over the past years suggests that proper name processing is not confined to this brain location.

Surgical removal of the frontal part of the left uncinate fasciculus, the structure connecting the LTP to the orbitofrontal cortex, results in selective difficulties in naming people (Papagno et al., 2011). This finding confirms the coworking of the LTP and frontal areas in processing proper names. But anomia for proper names can occur without frontal lobe damage. The contribution of the frontal lobe to proper name processing may thus be limited to specific tasks and conditions.

Clinical investigations were paralleled by neuroimaging studies. Using PET, Damasio et al. (1996) found that two main areas of significant activation distinguished naming faces from a baseline task requiring judging the orientation of unfamiliar faces presented either upright or upside down: the LTP and the right temporal pole (RTP). While activation of the LTP confirmed the results of the clinical investigation, activation of the RTP was interpreted as reflecting the face recognition process. A first follow-up study (Grabowski et al., 2001) obtained the same results as far as naming faces was concerned as well as when naming was required of pictures of famous landmarks. This finding was interpreted as evidence that the LTP is critical for retrieving the names of unique entities such as persons and landmarks. A further PET investigation by Damasio et al. (2004), however, yielded similar but more complex results. In this study, the areas of activation in naming faces (as compared to animals and tools) were the RTP, the left anterior sector of the superior temporal sulcus, the ventromedial prefrontal cortices, and the anterior cingulate. The authors argued that regions related to the processing of emotions (i.e., the ventromedial prefrontal cortices and anterior cingulate cortex) would be required because unique familiar faces, for most subjects, are emotionally salient stimuli. The activation of the LTP, however, only reached a marginal level of significance.

An activation of the LTP in face naming (and other tasks involving proper names, e.g., matching proper name with a face on multiple choice), although most often in connection with other areas, was shown in many functional magnetic resonance imaging studies (Gorno Tempini et al., 1998; Leveroni et al., 2000; Tsukiura et al., 2001, 2003; Rotshtein et al., 2005; Pourtois et al., 2005). The most original contribution of this group of studies has been to show that, while the left anterior temporal region is important for the retrieval of people's names irrespective of their familiarity, the right superior temporal and bilateral prefrontal areas are crucial for associating newly learned faces and names (Tsukiura et al., 2003).

Converging evidence about the role of the anterior temporal lobe and connected areas in proper name processing come from electrophysiological studies. Proverbio et al. (2001) showed that the tacit retrieval of a proper name's phonological form elicits a strong activation of left anterior temporal and left centrofrontal areas; the same task showed greater involvement of occipitotemporal areas with common names. A study conducted via direct cortical stimulation (Giussani et al., 2009) also underlines the role of inferior frontal areas. In this study, face-naming specific sites were found to be more extended with respect to those shown by neuroimaging, including the superior, medial, and inferior frontal lobe gyri, as well as the anterior part of the superior and medial temporal gyri.

The nature of the task employed, and, possibly, several, so far not completely investigated, factors may be the reason of

different empirical findings. In conclusion, as Tranel (2006) argues, "depending on factors such as the exact nature of the stimulus, task demands, and the nature of a particular individual's abilities, the same task might engage different convergence zones across relatively comparable individuals." Thus, as Semenza (2009) proposes, various aspects of proper name retrieval may be sustained by different structures differently participating in a complex network, which remains, at the present time, poorly understood.

Two Systems: Why?

Why did different name processing systems develop in the evolution of the human brain? The philosophical and linguistic theories mentioned in the introduction make clear that proper and common nouns serve two fundamentally different functions: categorization and individuation. Semenza (2006, 2009) argued that, in the primitive world it might have become increasingly important, for the sake of survival, not only to be able to categorize surrounding entities but also to label categories in a precise fashion. Using a precise name, e.g., 'lions' or 'swamps,' for a kind of ferocious cat and for a kind of dangerous place, might have, for example, saved conspecifics' lives by allowing quicker and more efficient descriptions and warning. The ability to single out, and call by a proper name, individual entities ('F' is a friend, 'E' is an enemy, 'P' is a dangerous place) might have served similar warning aims. Distinct functions may allow quicker and more precise processing. Those humans who more efficiently and unambiguously distinguished categories and individual entities might have had a greater chance of being winners in the scheme of natural selection.

These considerations remind of findings in the animal literature. For example, chicks discriminate with the right hemisphere between known and new, while they assign category with the left hemisphere (Vallortigara et al., 2008). Two systems can thus be envisaged as stemming from evolution: one for top-down control, taking care of category assignment and routine behavior, and one for bottom-up control, working for individual recognition and socially relevant stimuli. When language was acquired by humans, this distinction was recruited for the lexicon.

In the particular case of naming humans, Semenza (2006, 2009) further argued, additional social purposes, also useful for reproduction, might have determined an advantage for the individual gifted in this respect. This idea was further developed and given some empirical support. Simmons and Martin (2009) suggested that the LTP is specifically involved in supporting socially relevant conceptual knowledge, in particular by mediating associations between names and person-related semantic information. Using both conjunction and region of interest analyses, Simmons et al. (2010) found person-selective but not domain-general responses in both the left and the right anterior temporal lobe when subjects encoded semantic facts. These structures are also engaged in social conceptual processing. The anterior temporal lobes would work in unison with a wider social cognition system to support learning facts about other people. The fact that the anterior temporal lobe is involved in processing social conceptual knowledge generally may be accommodated with the fact that it also acts in processing information about unique entities, in particular information about faces, and, to a lesser extent, landmarks.

The social aspect of proper name processing, as mentioned above, may also, interact with age. Tsukiura et al. (2011) showed that the anterior temporal lobe showed greater activity for names of faces than for job titles, but there was no age difference in the activity in this region; functional connectivity between hippocampal and anterior temporal lobe activities in both retrieval tasks was, however, higher for young than for older adults. Ischebeck et al. (2011) showed that activation of the LTP in encoding proper names looked significantly stronger in older subjects than in a younger group. Semenza (2011) thus argued that social interaction apparently contributes to convey proper names processing toward areas closer to those supporting social cognition. Consistently with Simmons and Martin's (2009) view, the LTP may accumulate both social conceptual knowledge and information about unique entities, important for social interaction acquired in life. Its close and privileged connections with the frontal lobe and with the wider social cognition system would thus be reinforced throughout life. Relying on this system may help the elderly in overcoming the higher demands of proper name processing relative to processing of common names.

Proper Names in Clinical Practice

Naming with proper names has been used in clinical practice. Anomia disproportionately affecting proper names is a rather common early finding in AD. Semenza et al. (2003a) tested suspect patients, who did not yet meet the commonly accepted criteria for a diagnosis of AD on proper and common name retrieval. Seven months later, a subgroup of these patients was found to have developed the disease. This subgroup was compared with the remaining patients on neuropsychological assessment batteries that were administered the first time. Only proper name retrieval was found to be more deficient in patients who later developed AD. Delazer et al. (2003) showed that proper name anomia in AD is due to semantic deficits, to a degradation of phonological representations, as well as to problems in accessing the phonological representation. It is only this last cause that contributes to the problems in proper name retrieval experienced by normal elderly people. Access to semantic knowledge about famous people has also been shown to be vulnerable in patients in stages of AD (among many others, see Ahmed et al., 2008; Beeson et al., 1997).

Specific investigations were conducted to see whether the difficulty in naming people in minimal cognitive impairment (MCI) reflects problems associated with lexical access or with semantic access (Juncos-Rabadán et al., 2011, 2013). Semantic access was not impaired. These studies concluded that failure in phonological access may be the first step in the progression from MCI to AD as regards naming difficulties. The tip-of-the-tongue phenomenon for proper names may effectively discriminate MCI patients from normal controls. MCI thus seems to involve a greater deficit in transmission from semantic to phonological representations than that produced by normal aging.

Property: Anthropological Aspects

Chris Hann, Max Planck Institute for Social Anthropology, Halle, Germany

Abstract

The concept of property has been deployed in such specific ways in Western political philosophy, law, and economics that some anthropologists question its usefulness for comparative analysis. This article argues for its retention and the continued investigation of both 'real' and intangible property relations. Anthropological approaches challenge abstract models by exploring the sociocultural contexts in which property objects are held and exchanged, including the ways in which legal rights mesh with relations of power. In the era of neoliberal capitalism, anthropologists also need to reengage with world history and connect the specific claims of property to wider frameworks of citizenship.

Introduction

Property, a term used in everyday speech to refer to owned objects, is conventionally defined by scholars in terms of the rights held by persons (or groups of persons) in material and immaterial things, including other sentient beings and even other humans (notably when owned as slaves). It involves legal claims and has consequences for economic efficiency. Property is more than a technical institution, more than a relationship between persons and objects, and a great deal more than the right of a single owner to possess, use and alienate an object exclusively, though private property of this kind has been the standard of recent centuries. It expresses the fundamental norms and values of a society, such as equality, freedom and justice. Property thus has a long history in philosophy. The concept and the basic approaches to this institution in modern disciplines such as psychology, sociology, and economics have been shaped by particular intellectual traditions in Western Eurasia, and by the dominance of North Atlantic capitalist societies in recent centuries. For the proponents (or ideologists) of these societies, private property is central to liberty as well as to economic efficiency. For critics, such as Karl Marx, private ownership of the means of production is the basis of class inequality, which only collective ownership can overcome.

The power of this Marxist critique waned as social scientists studying industrial societies came to recognize that property was just one source of social inequality, and not necessarily the most important or enduring. Scholars have come to appreciate the dangers in applying either bourgeois or socialist models outside the regions and historical epochs for which they were developed. Some have come to question the value of the term 'property.' However, it seems safe to assure that all human societies regulate and reflect on their relations with different categories of things in their environments and transmit these understandings over time. In this sense, property is universal, a total social institution in the Maussian sense, 'embedded' in every social order (Hann, 1998). This article will explore what light the discipline of sociocultural anthropology has shed on property, past and present. Although this anthropology is a modern subject with a relatively short history, I shall organize my argument historically, initially by distinguishing between the evolutionist speculations of the nineteenth century and the ethnographic perspectives, which dominated in the twentieth. For much of this history, the principal focus of property research was land tenure ('real property'), but in recent decades, the study of intellectual property has gained in salience. I shall then turn to my own research in rural Eastern Europe to illustrate some of the central issues in more detail. With propertization invading ever new domains of social life and world economic institutions increasingly unstable in the first decades of the twenty-first century, I shall conclude by arguing that anthropologists are now well placed to renew their theoretical critique of a particular Western configuration.

Evolutionist Approaches

Property was a central concern of the legally trained scholars who played a key role in the emergence of anthropology (ethnology) as a distinctive field of inquiry in the nineteenth century. In England, the challenge was to make sense of how property was held in the most important of the colonies, India. In his *Ancient Law* (1861), Sir Henry Maine contributed the concept of a 'bundle of rights,' an invitation to disaggregation that has remained extremely useful to legal anthropologists and continues to be refined (von Benda-Beckmann et al., 2006). He emphasized that property rights were rights against other persons, i.e., they could only be understood in social context; at the same time, he was in no doubt that the rise of private property rights went hand in hand with the rise of civilization.

No less important was Lewis Henry Morgan's answer to the challenge of the New World, where the European colonists found societies more radically different from their own. The interpretation of property rights was central to these encounters. Morgan's sympathies were with the Iroquois and other native Americans, whose rights had been usurped by conquerors. In his magnum opus *Ancient Society* (1877), Morgan argued that the entire history of humanity could be traced as the history of property. He followed Jean-Jacques Rousseau in seeing private property as the original source of social inequality, rejecting the Lockean argument that property ownership could be justified in terms of the human labor invested.

The political conclusions of Morgan's work were drawn out by the early intellectuals of the socialist movement, above all

by Engels (1884). His evolutionary scheme was enshrined into the dogmas of historical materialism and eventually into Soviet anthropological science. Scholars in this school were expected to classify societies according to a unilineal scheme, in which the form of property holding was the key diagnostic. This was considered a rigorous science, an infinite improvement on Proudhon's facile claim that all property was theft. Ethnographers and historians were charged with documenting the degeneration from a pristine 'primitive communism,' in order to make credible the utopian ideology that promised a return to such egalitarianism in the communist future.

Not all evolutionist scholars accepted the postulates of the socialists. In Britain, James Frazer argued that *tapu* prohibitions in the Pacific and similar forms of 'superstition' all over the world had facilitated the evolution of private property, for him as for Maine a measure of human progress (Frazer, 1909). In Germany, Karl Bücher insisted that an 'individual search for food' preceded the emergence of any collectivist institutions (Spittler, 2008). Bücher was primarily an economic historian and not a fieldworker. His lectures in Leipzig in 1908 were attended by the young Bronisław Malinowski, who recognized that the debate about ancient forms of property could not be settled on the basis of the evidence available. Speculation about origins had to give way to scientific ethnography. This set the agenda for the rest of the twentieth century.

Ethnography and Diversification

Fieldworkers in the new paradigm undermined the simple binary between collective and individual, which had dominated so much earlier work. By looking more closely at what was going on in the major productive activities in the Trobriand Islands (Malinowski, 1935), or in the exchange of valuables (Malinowski, 1922; cf Mauss, 1924 [1990]), it was possible to recognize that both individuals and groups had rights, but that no party had a bundle of rights approximating private property in a highly commoditized economy based on the market and contract. Following this recognition, the critique of contemporary capitalist society faded into the background. Thus, the conceptual scheme applied by Max Gluckman (a political radical) in his celebrated study of Barotseland (1965) can be seen as a refinement of the framework developed by Malinowski (a political conservative) for the Trobriand Islands. Rather than resolving the contradictory conjectures of their nineteenth century predecessors, the anthropologists of the mid-twentieth century documented the contemporary complexity of land tenure. Their results were useful to the last generation of colonial administrators (Meek, 1946). Gluckman proposed that, while the rights to produce on specific plots were generally vested in particular households or persons, other rights were dispersed in a 'hierarchy of estates' of administration, typically ranging from a village headman to a paramount chief. None of these were owners in the Western sense – and friction was sure to arise if this resource, the basis of life, were to be treated as an alienable commodity. Around the same time, following a different intellectual route, Karl Polanyi argued that land (together with labor and money) was a 'fictitious commodity' (Polanyi, 1944).

The most important bridge between the new ethnography and the older concerns of the evolutionists was constructed by Jack Goody (1962, 1976). Working in the early 1950s in Northern Ghana, then the Gold Coast, Goody became interested in the way property of different types was transmitted, eventually distinguishing sub-Saharan African modes of 'devolution' from the more individualized forms of inheritance and 'heirship' that were characteristics of the plow economies of Europe and Asia (Eurasia). The dichotomy was to be seen in the principal form of marriage payment ('horizontal' bride-wealth in Africa versus 'vertical' dowry in Eurasia). It was also expressed in social structures (Eurasia was more hierarchical) and many aspects of culture (cuisine, flowers, etc.). Goody supplemented his own and other ethnographic studies with historical evidence and data from the Human Relations Area Files. However, this form of macrocomparison over an extended time frame attracted few followers. Goody's emphasis upon modes of property transmission paid insufficient attention to the relations of production for the taste of the neo-Marxist anthropologists who rose to prominence in the 1970s. He remained isolated thereafter, as the mainstream of the discipline came to emphasize the interpretations made possible through ethnographic encounters, and to shy away from anything, which smacked of evolutionism.

Theoretical trends in anthropology were reinforced by other factors, such as an apparent decline in the significance of inherited property in the era of welfare states, and the recognition that *access* and managerial *control* were as important as formal ownership in explaining the workings of mature capitalism. With the contraction of the agricultural sector, the study of real property lost its earlier overriding significance. Pioneering studies of hunter-gatherers that provided some ethnographic support for notions such as 'primitive communism' were duly noted, but they did not have the impact they would surely have had in the earlier epoch (Lee, 1979). A partial exception was the attention that was paid to contemporary challenges in managing 'common pool resources' (Bardhan and Ray, 2008). Whereas the ideologists of capitalism argued that a failure to institutionalize strong private property rights would lead inexorably to abuses and a 'tragedy of the commons,' anthropologists joined other scholars in showing that local communities were perfectly capable of working out communal solutions that were more efficient as well as more equitable than those generated by the market and private property. What was true for land also held in the marine sector, despite the greater difficulty in specifying sharp boundaries in this sector (Acheson, 2003).

These anthropological contributions tended to draw theoretically on the 'new institutional economics.' They were generally oriented toward solving problems of rational coordination in the present rather than pursuing long-term evolutionist arguments. These approaches have remained marginal to anthropological theorizing. Economists have remained implicitly or explicitly evolutionist, assuming that property regimes change whenever the benefits (in terms of allocative efficiency) are calculated to exceed the cost. Stephen Gudeman has vigorously challenged this reductionist perspective on property in the course of putting forward an

alternative general model, one which pays equal attention to the social bases of human communities or what he terms *mutuality* (2008: pp. 79–84). According to Gudeman, this mutuality, together with its pendant, the principle of the market, is present in all human societies, including our own.

If sociocultural anthropologists have cooperated with economists and political scientists to explore ways of regulating access to the material environment, they have consolidated their old alliances with lawyers and historians in other sectors. Much attention has been paid to intellectual property. If patents and trademarks emerged historically to serve a purpose in the real economy, the function of a prominent consumer brand in the twenty-first century often seems entirely detached from any such moorings. It is explicable only in another sphere, that of *symbolic value*. Yet precisely because of their importance in shaping personal and collective identities, these brands have massive consequences for productive systems and the distribution of income.

The study of intangible property rights is not new in anthropology. Earlier researchers had pointed to the importance of symbols and secret, sacred knowledge among remote, nonliterate peoples. Under neoliberal capitalism, the descendants of these peoples are likely to find themselves obliged to register such symbols as cultural heritage and thus the exclusive property of their group. Bowing to the hegemonic legal forms, no matter how alien to traditional norms, is often the only way for vulnerable groups to defend their interests. This 'propertization' of cultural knowledge has major implications for the holders of rights at both group and individual levels (Brown, 2003). Anthropologists are generally disposed to supporting the claims of indigenous groups. However, ethical issues may arise: should group members who have permanently moved away retain their rights and be able to bequeath them? What about long-term residents who do not belong to the indigenous group but may be equally poor and marginalized: are they to be excluded from title and the ensuing income streams?

Propertization here refers to the accelerating process of extending the logic of exclusive property rights to new kinds of 'thing,' ranging from body parts to the genome and 'indigenous scientific knowledge.' If Polanyi were alive today, he would surely add human body parts to his list of fictitious commodities (see B. Parry, 2004). He might also be tempted to include the scientific knowledge on which new medical technologies depend. New possibilities of surrogacy are enabling for some but they may be exploitative for others. Progress in genetic knowledge has generated contestation over ownership at multiple levels in the unique case of Iceland (Pálsson and Harðardóttir, 2002). The internet has become a key forum both for the implementation of new forms of property and for creative countercurrents in the spirit of a new commons. For example, copyright claims in the field of popular music, have been countered 'from below' through innovative use of the Net, just as the excluded have always subverted the formal property rights of the powerful throughout history (Hann, 2007). But this may be too sanguine an interpretation of current trends. The capitalist private property configuration continues to dominate and to spread relentlessly, legitimized by schools in economic thought which attach the highest importance to strong property rights. Flexible systems of customary landholding or marine tenure are routinely dismissed in favor of new fences or, where fences are impossible, by 'individual transferable quotas' of fish, based on property dogma rather than a substantive concern to manage resources efficiently and equitably (Minnegal and Dwyer, 2011).

In the light of these trends, one might expect to find property reassuming the central role it played for the anthropological vision of Morgan in the nineteenth century. This has not happened so far. The reasons may have to do with increased specialization, which makes it hard for contemporary anthropologists to investigate property as a total social fact. Thus anthropologists with an economics background have concentrated on questions of allocative efficiency (Gilman and Hunt, 1998), while colleagues with a legal background are more likely to emphasize the negotiation of claims, persuasion, and symbolic communication (Rose, 1994). Legal anthropologists have recently distinguished four 'layers' in formulating a comprehensive framework for the investigation of property: the wider cultural tradition, legal regulations, social relations, and finally 'property practices' (von Benda-Beckmann et al., 2006). However, this apparatus is explicitly advanced as a heuristic and not as a contribution to theory. The authors venture no claim as to which layers are more likely to initiate changes in a property system, or the circumstances in which layers may coexist despite evident disharmony between them. Among the great majority of anthropologists, who have no training in either law or economics, it is interesting to note that the term property seems to be fading. This trend is illustrated in the work of Marilyn Strathern, who is suspicious of property because of its Western baggage (1999). For her, Melanesia is so radically different from the West that it makes no sense to persist with the established terms. The Melanesian person is a 'dividual' rather than a rights-holding Western individual. Others have argued in a similar vein that not even 'things' or 'relations' are valid terms cross-culturally, and suggested that 'value' be a more appropriate focus of anthropological research (Verdery and Humphrey, 2004; Verdery, 2003). Alternatives such as ownership and appropriation are held to be less contaminated by Western history (Strang and Busse, 2011).

(Post-)Socialist Transformations of 'Real Property'

At this point let me step back from these general developments and illustrate how one anthropologist found himself obliged to address issues of property in the course of longitudinal studies of land tenure in rural Eastern Europe during and after socialism. The collectivization of land in the former Soviet Union and allied states was a world-historical event that is frequently invoked by the proponents of private property ideologies. Soviet law did not need the category 'real estate,' since it declared that land was owned by the state and not available for alienation (though it could be transferred between socialist enterprises). In addition to the brutality and loss of life occasioned by collectivization in the USSR of the 1930s, critics have alleged that the new institutions of cooperative (*kolkhoz*) and state (*sovkhoz*) farms exemplified the inefficiency of collective forms of property holding. Only

on their own personal (household) plots did villagers have an incentive to work efficiently because they themselves would reap the benefits, either in terms of subsistence goods, or through sales on local markets, and frequently both. According to the stereotype, all things outside this domestic sphere were considered fair game for pilfering and no one had any incentives to use them efficiently; this was obviously detrimental to overall economic performance and led eventually to the collapse of the entire bloc.

In my fieldwork in post-collectivization Hungary, I often heard similar negative opinions expressed by villagers; but my analysis led me to qualify these antisocialist clichés (Hann, 1980). The community of Tázlár is located in a region of the Great Hungarian Plain, which was resettled in the late nineteenth century. Capitalism was developing in this era, but there were not enough industrial jobs for an expanding rural population. As a result, regions of poor natural endowment were colonized as a kind of 'internal frontier.' Immigrants purchased parcels of land as private property. Most of them built their cottages on their plot; a nuclear center was not consolidated until the socialist era. Property boundaries were unambiguous (aided by the late Habsburg cadastral survey) and there were no complex 'hierarchies of estates.' In a region that remained economically backward, the acreage one owned was the prime determinant of both economic capacity and social status.

The significance of real property was temporarily inverted in the Stalinist years, when so-called *kuláks* (rich peasants) became the targets of political campaigns and leveling was imposed by force. Mass collectivization was eventually implemented around 1960. Most villagers signed up for one of the new cooperatives with great reluctance. Those with above-average holdings were devastated to find themselves in an association on a par with fellow villagers who had previously possessed little or nothing. However, not all property rights were eliminated. After joining one of the new cooperatives, villagers retained title to their plots. These rights continued to be transmitted through inheritance, though few took the trouble to visit the necessary offices to update the registers. These legal niceties seemed irrelevant in the face of Communist Party power. Tázlár diverged from the standard *kolkhoz* pattern in the extent to which villagers were able to continue farming their own plots as a household unit. This was a pragmatic concession due to the scattered settlement pattern. However, here too there was a commitment to amalgamating fields eventually, to facilitate more rational, mechanized cultivation. Population decline as some villagers left permanently for new jobs in socialist towns facilitated such *remembrement*. Where plots were appropriated, their owners were always offered alternative fields elsewhere. In short, the old property regime was not suppressed completely, but private transactions of land were precluded. Power was in the hands of the cooperative, the leaders of which were in practice compelled to follow policies laid down by authorities external to the village, controlled ultimately by the Communist Party. We could theorize this in Gluckman's terms as a socialist 'hierarchy of estates' (Humphrey, 1983).

With the introduction of the 'New Economic Mechanism' in 1968, the socialist cooperatives were encouraged to take further steps to support the household farming of their members. The mechanized sector under collective cultivation specialized in the production of grain and fodder; in Tázlár it benefited from state subsidies paid to areas of poor natural endowment. Much of the output was sold to households to support the labor-intensive raising of animals. This was a productive symbiosis. In 1974, the separate cooperatives merged to form a single association. Despite the emergence of a stratum of professional leaders, policies in the 1980s continued to support the household sector. Presocialist property inequalities in terms of land ownership ceased to be of much significance, but new ones appeared as successful households built bathrooms and two-storey houses and purchased cars. Urban intellectuals sniffed at what they considered to be a frenzy of accumulation in the last decades of socialism (I did too). Yet for many, this symbiosis between household and cooperative offered an escape from poverty, and the unequal rewards could be justified in terms of unequal labor inputs. They did not depend on unequal access to the means of production. Arguably, this was a pragmatic balance of the main 'forms of integration' identified by Karl Polanyi, a native of Hungary (Polanyi, 1944). The demotion of property respected the above-noted dictum of his substantivist school that land was a 'fictitious commodity.' At the same time, the impressive economic expansion of the last decades of socialism refuted the dogmas of bourgeois property ideologies: property rights in the field of production were decidedly fuzzy, yet output increased impressively (just as it did later in China following that country's opening to the market). Villagers worked out pragmatic ways to combine large-scale and small-scale production, and found it perfectly rational to work long hours to accumulate private property in the realm of consumption. In this way, the socialist hierarchy of estates of administration was softened and became responsive to local preferences. Yet this did not mean that villagers warmed to their new institutions and abandoned their historically formed attachment to an ideal of full private ownership.

I contrasted this Hungarian situation with what I found in a follow-up study of a community in rural Poland (it was located in the center of the former province of Galicia, where Malinowski was born and grew up). For political reasons, following the turning point of 1956, the socialist government in Poland was unable to implement collectivization. The old pattern of family farming persisted. However, with the state committed to socialist goals in the industrial sector, modernization of the rural sector was hardly a priority. As a result, farming technologies remained backward, productivity levels low, and the opportunities for private accumulation very limited. Polish farmers had somewhat more secure rights of possession than their Hungarian counterparts, but they too were not free to expand their holdings, since the land market was strictly controlled. In short, the non-collectivized farmers in Poland were a lot worse off than the villagers who benefited from the pragmatic compromises struck in post-collectivization Hungary (Hann, 1985).

The collapse of socialism was immediately accompanied by a radical change in the property system, which affected all sectors of the economy. The whole world is familiar with the

rapid emergence of a new class of Russian billionaires in the wake of privatization in the energy sector. Anthropologists have documented the social and cultural consequences of the 'unmaking' of the Soviet economy more generally (Humphrey, 2002). Legal scholars have drawn attention to the enormous difficulty of creating effective private 'property bundles' from the mass of former state or cooperative assets. For example, many store windows in Moscow in the 1990s remained empty because of a 'tragedy of the anticommons' (Heller, 1998). This problem, the mirror of the more familiar tragedy of the commons, was one of underutilization rather than excessive exploitation of a natural resource. The suboptimal use of urban real estate resulted from the dispersal of property rights to multiple stakeholders (generally persons of influence under the old regime). More concentration of core rights in a single owner would, according to Heller, have led to economically more efficient outcomes.

Anthropologists have tended to base their fieldwork in the countryside, where the property bundles are different. In most of the former Soviet Union, as in Eastern Germany, land is still farmed in large units based on the old *kolkoz* and *sovkoz* (Hann et al., 2003). Legal privatization has not led to a structure of family farmers. Outcomes are shaped primarily by local power relations and many new 'owners' do not even bother to identify the boundaries of their holdings (Yalcin-Heckmann, 2010). Elsewhere, in many parts of Eastern Europe, plots were returned to their former owners, respecting original boundaries. This led to enormous social problems as well as economic irrationalities (Hann, 1993; Verdery, 2003). Hungary opted for a 'compensation' path that fell short of guaranteeing restitution of original holdings, in order to avoid losing the economic benefits of amalgamated fields. Even so, possession of title deeds suddenly reassumed the significance it had lost under socialism. Many in Tázlár felt emotionally compelled to claim the plots farmed by their forebears, even when this seemed irrational in purely economic terms (given poor soils, the withdrawal of state subsidies, the collapse of the supportive cooperative and of product markets in other ex-socialist countries). In short, an emphasis on property rights displaced the late socialist emphasis on expanding output; production has declined considerably since the halcyon days of the cooperative; large areas of Tázlár are no longer cultivated at all.

After Hungary joined the EU, a minority of the new private farmers has been able to benefit from this new source of subsidy. The EU supports specific branches of production and it also pays owners to maintain rural environments, which may entail leaving land fallow. Some high value crops, notably vineyards, are nowadays tended by their private owners with a dedication that is hard to imagine on the part of a socialist brigade leader (even if this leader had material incentives to improve his stewardship). Yet many private owners have difficulty disposing of their wine and bemoan the lack of a cooperative to assist them in standardizing a product to facilitate marketing. Some who were most critical of the pragmatic form of cooperative, which prevailed in this region of Hungary before 1990 would now like to reinvent it. They recognize that their rights as private owners (a powerful ideology, which prevented them from positively embracing socialist hierarchy) are now constrained by new 'hierarchies of estates' reaching beyond Budapest to Brussels. This 'tragedy of the privates' (Hann, 2006) differs from the above-mentioned 'tragedy of the anticommons.' According to the property lawyer Heller's analysis of the latter, the solution lies in more complete bundles of private property rights. However, in the case of rural real estate, I argue for the superiority of the socialist system, which brought land into *de facto* communal ownership, managed by a collective institution that was gradually brought under local control. The property lawyer and the anthropologist can agree that it is insufficient to insist on the 'clarity' of property rights and to blame the failures of 'transition' on factors such as corruption and inadequate property registers and legal procedures. But for Heller, the problem is to specify the optimal content of the property bundle. He takes it for granted that a system based on private, exclusive rights will be an economic improvement on Soviet law, in which the category of real estate was lacking. The anthropologist questions this initial bias of the Western lawyer, just as Gudeman (2008) questions the reductionism of the Western economists, and instead probes more deeply into the social consequences of the destruction of socialist institutions at the local level.

This is thus a complex situation, arguably as complex as land tenure among the Trobriand Islanders, studied by Malinowski. Anthropologists have struggled to place these post-socialist transformations in the context of world history; the history of their own discipline in the twentieth century has not been much help in this. According to the theories of the anthropologists in the wake of Malinowski and Gluckman, the 'individual versus collective' dichotomy was a misconceived Western imposition on preindustrial land tenure systems. Actually, existing property systems took the form of hierarchies of rights, combining the personal, the familial (household), the village community, etc. But tell this to an East European villager whose collective farm is broken up as fences are (re)built along the old boundaries, and he might well respond: 'claptrap.' The fact is that these fields have been privatized. The contrast in Tázlár is even clearer to the villagers than the imposition of collectivization in an earlier generation. Here, as elsewhere, for a small minority private ownership of the means of production has again become lucrative, while the majority has paid a high price. When pursuing these questions in Tázlár more than a decade after the end of socialism, many villagers answered with reference to wider frameworks, including their *entitlements* as citizens. For many, the formal restitution of some rights to land had brought no benefit at all, especially if, as a result of the demise of the cooperative, the household no longer had any source of regular income. Often, a minimal state pension was now the key to survival, analogous to the ownership of a parcel of land for their ancestors (Hann, 2006).

As with the 'tragedy of the commons' thesis discussed above, collective property does not have to mean fuzziness and confusion. In Tázlár in the 1970s, everyone knew the boundaries of the new collective fields, and respected the power of the cooperative to redistribute land that had been abandoned by urban migrants. Some of the collective activities were not well organized and political factors interfered from time to time – the cooperatives had many imperfections. But it needs to be recalled that socialist property systems were designed to be different from the Western configuration, and not to simulate

the economic outcome of a system which prioritized private ownership. In practice, few anthropologists have been as charitable toward this socialist alternative as they have toward different ontologies in remote Melanesia. There is no evidence that centrally planned economies had higher levels of corruption than their Western capitalist equivalents, with their well-oiled machinery of bribes and kickbacks. Productivity per unit of labor may have been inferior, but the other side of this coin was the absence of unemployment and high levels of mutuality at the workplace and in the community. Social inequalities increased considerably in the later socialist decades, as more and more 'things' could be owned as private property and passed on to the next generation. But so long as the great bulk of the means of production and financial institutions were owned and controlled collectively, inequalities were held in check.

Conclusion

There was an unfortunate disjuncture between the trends in anthropological theorizing, as summarized in section III, and the trend which set in during the last two decades of the twentieth century in global political economy, accentuated by the end of the Cold War and the extension of capitalism into the former Soviet bloc. In anthropology, the neo-Marxist energies were largely spent when Ronald Reagan and Margaret Thatcher inaugurated the era of neoliberalism, with policies that emphasized the privatization of industries, which had come under some form of collective or state ownership. Social inequalities increased dramatically, in part due to reductions in inheritance taxes. Property was transparently at the heart of social clearages. Yet anthropologists have not seized the opportunity. Some, in partnership with legal scholars, have investigated new forms of intangible propertization, but by and large anthropologists have left the big picture of unequal distribution to other disciplines.

I have argued that they have nonetheless made a useful contribution, above all by insisting on the historicity of Western property theories, and on the dangers in deploying (even within Western societies) simple dichotomies such as that between collective and individual. The case for complexity can readily be strengthened by extending the notion of property beyond its familiar referents, material, and immaterial. It is possible, for example, to justify a range of 'natural' inequalities if we take the view that celebrities such as Clint Eastwood *own* their remarkable bodies and are thus entitled to the income streams that being Clint Eastwood generates. The resulting inequalities can be countered by laws that provide all citizens with a range of entitlements, e.g., in the event of their falling sick or being unable to find employment. For many, to extend the term property to such general entitlements is to go too far beyond its established use. Yet ordinary people are likely to make exactly this sort of comparison when comparing their well-being under different regimes. At the very least, a right that is not vested in all citizens but in particular families, such as the right of a man to pass on his job at the Bhilai steelworks to his son (Parry, in press), should be considered as a property right, because it functions in the same way that rights to inherit real property used to function before the coming of industry.

In conclusion, we must remember that ideas about property have been of considerable significance in many intellectual traditions for many thousands of years. Sociocultural anthropologists began by engaging with European speculations about origins, but they have not fulfilled the early *historical* aspiration to take property institutions as a prism for understanding human social evolution. They have done rather better when it comes to documenting the diversity of property institutions and *cultural* variation in the very definition of its components (person, thing, etc.) as well as in the configuration. But this can be pushed too far: to emphasize unique local ontologies and the sheer inapplicability of any Western categories can be disabling. The modern anthropologists' success, based on micro, ethnographic studies, may have hindered their ability to mount a *sociopolitical* critique of property in terms of the stark, brutal inequalities it continues to sustain. In this sense, we need to recover the simplicity of property. Taken together, the works of the last century and a half have made substantial contributions, but it is time to develop a new synthesis that would draw the historical, the cultural, and the sociopolitical dimensions of property together.

Property Crime: Victimization and Trends

Jan Van Dijk, Tilburg University, Tilburg, The Netherlands

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The best sources of information on property crimes are victimization surveys. Using the results of the International Crime Victims Survey (ICVS) conducted once or more in over 80 countries from all world regions, an overview is given on rates of victimization by burglary, other personal theft, vehicle-related theft, and consumer fraud, including e-fraud. Distributions of victimization are explained as resulting from differential opportunities for crimes across regions. Results of the ICVS provide evidence of universal drops in property crimes in Western countries over the last 10 years. These drops are interpreted as resulting from improved security against property crimes as illustrated by the proven impact of security measures on the falls in household burglaries and car thefts.

Introduction

Property crime is and always has been one of the most pervasive categories of crime. It can loosely be defined as crimes directed at the illegal appropriation of other people's material goods. It includes different types of theft such as vehicle theft, pickpocketing and shoplifting, as well as various forms of fraud, including e-fraud and burglaries in households or commercial premises. In this article, we will discuss the most common types of property theft but exclude property crimes involving the use of violence against persons (robberies) and vandalism (destruction of property).

Figures of crime recorded by the police depend on the number of crimes reported by victims to the police. As known, a large proportion of crimes are not reported to the police or not recorded by them (generally known as the 'dark numbers' of crime). This holds also true for a large proportion of property crimes. In this article, the volume and trends in property crimes will therefore be described using results of victimization surveys among the public rather than official figures of crimes recorded by the police. Victimization surveys take a sample of the population (usually householders) to ask them if in the recent past they have been a victim of crime, whether or not they reported what happened to the police. Several studies have shown that survey-based estimates can give a more reliable picture of the volume and trends of crime than police figures. The most important early victimization survey is the National Crime Victimization Survey (NCVS) in the USA. Victimization surveys have since been conducted in most other Western countries and many Latin American countries as well (Aebi and Linde, 2012). In 1988, a standardized victimization survey was launched, called the International Crime Victims Survey (ICVS). This survey has been repeated in five major sweeps in a selection of over 80 countries selected from all world regions (Van Dijk et al., 2007; Van Dijk, 2008). Its results are acknowledged as the most authoritative source of comparative information on levels of crime (Lynch, 2006). The ICVS results will be used in this article to describe the volume and trends in victimization by main types of property crime across world regions. We will first present data on the prevalence of victimization by burglaries, other thefts, consumer frauds including e-fraud, vehicle-related crimes, and crimes against businesses. Next we will discuss trends in property crimes over time. Finally we will discuss the key determinants of the distribution and trends of these crimes.

The Prevalence of Burglary Victimization

Burglary in a dwelling is a universally frequently occurring type of property crime with a high impact on the victims (Mawby, 2001). The consequences of burglary in terms of monetary value may vary widely in different contexts. While in the industrialized world burglars frequently steal objects of a high value, such as audio/video equipment, jewelry, or computers, burglary in developing countries is often aimed at stealing cattle, food, house appliances, linen, or cutlery. Regardless of the economic losses, victims regard burglaries as very serious since it is a violation of their privacy in the domestic sphere.

The ICVS questionnaire asks respondents whether anyone did actually get into their house or flat without permission and steal or try to steal something. **Figure 1** shows the regional, 1-year victimization rates for domestic burglary in urban areas.

ICVS results show that on average one in four households in urban areas is visited by a burglar at least once annually. Households in urban Africa, Latin America, and Oceania (Australia, New Zealand) are most at risk. The European, Asian, and North American regions showed risks below the global average. The high prevalence in Africa is confirmed by regional studies (Afrobarometer, 2004; UNODC, 2005). Police-recorded burglary as recorded by the UN Crime Surveys, was highest in Australia, while the ICVS results indicate that the most affected regions were, as said, Africa and Latin America, which in turn showed the lowest rates in police data. In our view, rates of police-recorded burglaries give no useful information on the actual prevalence of burglary across regions or countries.

Other Personal Thefts

The ICVS contains a question on experiences with personal theft such as theft of purses, wallets, clothing, or equipment. Victims of such thefts are asked whether they were carrying

Figure 1 Percentages of public in urban areas victimized by household burglary during the past 12 months, by world region. Source: ICVS, 1996–2005; Van Dijk, J.J.M., 2008. The World of Crime: Breaking the Silence on Problems of Security, Justice, and Development across the World. SAGE Publications, Los Angeles.

what was stolen. Those answering in the affirmative are classified as victims of pickpocketing. Figure 2 shows the regional rates.

The distribution of regional rates of pickpocketing is somewhat exceptional. The crime of pickpocketing seems comparatively rare in North America and Australia/New Zealand. The countries of Eastern Europe find themselves in an unusual high place, at the same level as Latin America, Asia, and Africa. Pickpocketing is three times more common in Eastern Europe than in Western Europe with rates in Central Europe lying somewhere in between. This high position of Eastern Europe differs from the more modest positions of the region on the world rankings for other types of property crimes. A possible explanation for the special distribution of pickpocketing is differences in the common modes of mass transportation. In regions and countries that rely heavily on public transportation such as trains and city trams, there are more opportunities for pickpocketing than in countries where cars are the dominant form of transportation.

Consumer Fraud

The ICVS asks whether the respondent had been the victim of a consumer fraud over the past year, focusing on cheating in commerce or the services industry. The most common frauds occurred in shops or during construction or repair work or in a garage. Consumer fraud shows higher average rates and more variation across regions than any other type of crime. Thirty-eight percent of the respondents from Eastern Europe actually experienced a consumer fraud of this type, followed by 30% in Asia and 26% in Africa. In Australia and New Zealand consumer fraud is almost unknown. The comparatively high rates in Eastern Europe have been interpreted as a side effect of

Figure 2 Percentages of public in urban areas victimized by pickpocketing during the past 12 months, by region. Source: ICVS, 1996–2000; Van Dijk, J.J.M., 2008. The World of Crime: Breaking the Silence on Problems of Security, Justice, and Development across the World. SAGE Publications, Los Angeles.

the transition from a planned economy – coupled by a huge black market – toward a regulated market economy (Zvekic, 1998). The extent of consumer fraud appears to be higher in newly emerging market economies where consumer protection is underdeveloped and regulation of markets is weaker.

Victims of consumer fraud were asked in which type of situation the incident had taken place, including while shopping on the Internet. At country level, 45% of victims said the fraud had taken place in a shop. Eleven percent mentioned either building or construction work or a garage. Nine percent mentioned shopping online. This implies that 1% of the national respondents of the participating countries have been victimized by a fraud on Internet. Among city inhabitants the victimization rate was 1.5%. The 2003 NCVS of the USA reported a national victimization rate of credit card theft of 2.4%. Recent surveys in the United Kingdom showed rates went up from 3.7% in 2009 to 6.4% in 2009 (Walker et al., 2009). Internet-based frauds have now apparently reached prevalence rates that are similar to those of common crimes as car theft or pickpocketing.

Car Theft and Joyriding

While a number of cars are stolen for the purpose of 'joyriding' or to commit other crimes, others are either dismantled or sold on domestic or transnational markets for stolen vehicles. In Australia and North America around 80% of the stolen cars are eventually recovered. In these regions most cases of car theft comprise 'joyriding.' In most European and Asian countries only on average around half of stolen cars are recovered. In many cases cars recovered after being stolen are seriously damaged. In the judgment of victims, both car theft and joyriding are judged to be among the most serious forms of conventional crimes covered by the ICVS (Van Dijk, 1999). Apparently many owners are much attached to their cars and resent loosing them or finding them damaged due to a criminal act.

Figure 3 shows the regional rates of victimization by car theft, including joyriding.

Regional rates for car theft show a distribution across regions that is almost the mirror image of victimization by burglary. Rates in North America and Oceania are the highest. Lowest rates are found in Africa, Eastern Europe, and Asia. Obviously the level of car theft as of other car-related crimes is strongly dependent on national rates of car ownership. Where more households own cars, the prevalence of such crimes is higher. Car crimes are a prime example of how affluence-related opportunities of crime drive up the volume of property crime. To give a better picture of the risks for owners, rates are often calculated of the percentages of owners victimized by these crimes in the course of a year. Car owners' victimization rates for car theft are, of course, higher than the general population's victimization rates for car theft. The differences are most marked in regions where car ownership is comparatively low (Africa and Latin America).

Other Vehicle Theft

In several European and Asian cities, bicycles are among the most important modes of transportation. Bicycle theft provides yet another example of how the levels and nature of volume crime are shaped by the dominant modes of transportation in a country. Bicycle theft, as car theft, appears to be clearly driven by ownership levels, with the Netherlands in top position. Even in otherwise low-crime countries such as China and Japan, the general availability of bicycles generates high rates of bicycle theft as 'crimes of expediency.' The analysis reveals a clear *exponential* relationship between bicycle ownership and theft. If bicycle theft surpasses critical levels, a chain reaction seems to be set into motion by victims committing themselves to stealing – or to knowingly buying from fences – to replace the stolen bicycle. This phenomenon of 'compensatory stealing' of

Figure 3 Percentages of the public in urban areas victimized by car theft or joyriding during the past 12 months per region. Source: ICVS, 1996–2005; Van Dijk, J.J.M., 2008. The World of Crime: Breaking the Silence on Problems of Security, Justice, and Development across the World. SAGE Publications, Los Angeles.

bicycles has been well documented among student populations in the Netherlands (Felson, 1997).

Equally strong relationships have been demonstrated between motorcycle ownership and motorcycle theft. Motorcycle theft also provides an interesting example of how the introduction of new safety regulations and ensuing changes in behavioral patterns yield an unexpected crime prevention bonus. In the 1970s, several countries introduced safety laws requiring motorcyclists to wear helmets. Offenders wanting to steal a motorcycle now had to go equipped with a helmet or they would be spotted quickly. The enactment of the new helmets legislation has led to dramatic declines in motorcycle thefts in several countries (Mayhew et al., 1989).

The Heavy Crime Burden of the Business Sector

Victimization through common crimes is usually associated with the public at large. In reality the business sector is the prime target group of many forms of property crime. Crimes committed against businesses are not accurately reflected in police figures for the same reason as other crimes. To collect better information on 'commercial victimization' across countries special victimization surveys among businesses have been conducted. The International Crime Business Survey was carried out in 1992 among, initially, samples of retailers in nine European countries, Australia, and South Africa (Walker, 1994; Van Dijk and Terlouw, 1996; Naudee et al., 1999). The questionnaire was modeled after the ICVS and contained a similar range of conventional crimes. The results show that most retail businesses are regularly victimized by conventional crimes. The corporate victimization percentages are many times higher than those of private persons. This is not only true for theft (e.g., shoplifting) but for burglary as well. Studies of the total costs of crime have indicated that the total damages resulting from property crime of the corporate sector surpass those of the public at large (Mayhew, 2003).

Recently, international accounting firms have taken up an interest in crime surveying. A victimization survey of companies across the world indicates that 45% of all respondents had suffered from some form of economic crime in the course of the past 2 years. These global results indicate an increase on previous such surveys which holds across regions (PriceWaterhouseCoopers, 2005). Prevalence rates remained the highest by far among companies in Africa. A similar survey of global companies in 2004 found that just under one half of respondents (47%) had experienced a significant fraud in the last year (Ernst and Young, 2004). According to these two surveys half or more of the perpetrators of economic crimes are company insiders (managers or staff).

Determinants of Property Crime

Urbanization and Crime

A consistent finding in traditional analyses of police-recorded crime rates was that recorded crime is more prevalent in large cities than in rural areas (Beirne, 1993). In many European countries, for example, the number of police-recorded crimes is at least twice as high per 1000 inhabitants in the larger cities as in the countryside. Data from NCVSs have confirmed the urban–rural crime divide. The fairly consistent relationship between urbanization and levels of volume crime at both individual and country level calls for further theoretical reflection. According to 'routine activity theory,' crime rates are determined by the confluence in space and time of pools of motivated offenders and viable opportunities to commit crimes (Cohen and Felson, 1979). This theoretical perspective can help to explain the urban–rural crime divide. While poverty by itself may not be a major cause of crime – in Asia rates of property crimes remain low in even the poorest countries – the propensity to offend is higher among young, disenfranchised males than among other groups. Other factors possibly contributing to higher levels of offending in large cities are weakened family ties and other forms of social cohesiveness and the concentration of people from different cultures. At the same time, and perhaps more importantly, targets of crime such as cars and other luxury goods are abundantly available in large cities while the daily routines of urban dwellers may leave these targets of crime less 'socially well guarded.' Typical for large cities, for example, are shopping malls and large-scale school complexes where 'natural surveillance' is weak. City life generally brings people into contact more often with strangers, including potential offenders. This confluence of criminogenic push and pull factors in large cities goes some way to explain the higher crime rates in big cities (Felson, 1997).

Demographics and Crime

Thefts, burglaries, assaults, and other forms of volume crime are to a large extent youth-related phenomena. In all countries, the majority of offenders as well as a disproportionately large proportion of victims are males between 15 and 30 years of age (Adler et al., 1998). The ICVS database allows comparisons of the victimization rates of various age groups for different types of crime. Universally, younger people (24 years of age or less) are markedly more at risk than older ones, defying the stereotypical notion of offenders preying on the elderly. Findings on offending show the same age-related patterns and profiles. Among 12–18 year olds in many countries, engagement in forms of juvenile delinquency is very common among teenagers, especially boys. Self-reported delinquency surveys, another method for collecting information on crime independently from the police, show that the peak of young people's criminal activities lies between 15 and 18 years (Bartelet, 2004). Overrepresentation of young males among offenders is attributed by criminologists to weak social integration during the transition from childhood to adulthood (Wilson and Herrnstein, 1985). Many studies report steep declines in criminal involvement after the age of 25 for property crimes and 30 for violent crime (called 'aging out' phenomenon).

Analyses of ICVS data on victimization by common crime confirm that overall victimization rates are significantly higher in societies with more young males such as most African and Latin American countries. Previous analyses of global ICVS victimization data have shown that the macro factors of urbanization and age structure combined explain half of the variation in national victimization rates (Van Dijk, 2008). Put

differently, if all world populations were roughly similar in degree of urbanization and age structure, national differences in levels of crime would be reduced by half.

Affluence and Crime

From an economic perspective, it seems self-evident that for those living in extreme poverty, the commission of profitable offenses presents a tempting alternative source of income. This line of thinking, known as anomia or strain theories, has dominated the twentieth-century criminology. Empirical studies do not confirm, however, any straightforward relationship between poverty and crime at the macrolevel (Belknap, 1989; Van Wilsem, 2003). For a proper understanding of crime rates the prevalence of poor or unemployed people in a population is not the only relevant factor. The prevalence of potential victim populations and of situational factors facilitating crime must also be taken into consideration (Van Dijk, 1994). Some of these factors are positively related to affluence. One such factor is, as mentioned above, the availability of suitable targets of property crime. Affluence brings into mass circulation goods that fit the acronym CRAVED: Concealable, Removable, Available, Valuable, Enjoyable, and Disposable (Clarke, 1999). Examples of such craved goods driving up crime rates in modern affluent societies are mobile phones (Harrington and Mayhew, 2001). Affluence is in many parts of the world accompanied by urbanization and ensuing weakening of social cohesiveness. These factors drive up levels of property crimes, regardless of the income situation among local pools of potential offenders.

According to conventional criminological theories, fewer people will be motivationally inclined to engage in offending if societies become more prosperous. However, crime trends in developed countries over the past 50 years have not been in line with this optimistic model of crime prevention through development. Trends in crime over time in the Western world are positively related to levels of affluence. All developed countries experiencing 'economic miracles' in the 1960s after recovering from the World War II saw their crime rates surging, with crime rates multiplying fivefold or more in some countries (Laycock, 2001). In conclusion, the crime reducing effects of affluence through a reduction of the motivation to offend for economic reasons are more than offset by the increased availability of opportunities to commit profitable crimes.

Trends in Property Crime over Time

The first ICVS was carried out in 1989 and repeated four times till 2005 in a large group of countries. For Johannesburg, Buenos Aires, Australia, Canada, and 11 European countries data are available from all five sweeps. The results show that levels of conventional crime have in most parts of the world continued to rise up to the mid-1990s. This rise in crime has started in the 1960s or 1970s. After reaching peaks between 1995 and 2000, national crime rates have fallen significantly across the Western world. Figure 4 shows results for victimization rates by any crime (largely determined by property crime).

Since the third sweep in the mid-1990s victimization by crime has dropped significantly nearly everywhere in the participating nations. The falls in crime are by no means a unique American phenomenon as previously claimed. The

Figure 4 Trends in crime experienced by national or city populations during 1988–2005; overall victimization rates in Argentina (Buenos Aires), South Africa (Johannesburg), Australia, USA, Canada, and Europe (nine countries). Source: ICVS, 1988–2005.

falls are near universal in the industrialized nations and have also happened in the cities of Johannesburg and Buenos Aires.

Many different explanations have been put forward for the drop in crime in the USA (Blumstein and Wallman, 2006; Zimring, 2006). Factors that are special for the USA such as zero-tolerance policing, mass incarceration, or the end of the crack cocaine epidemic cannot explain the universal drops in crime across the Western world (Van Dijk et al., 2012). The universal drops in the two most common types of property crime, car theft and household burglary, seem primarily to have been the result of improved security as will be illustrated below.

Levels of car theft have gone up universally in Western nations from 1960 onward in tandem with rates of car ownership. Although car ownership levels are stable or still rising, thefts of cars have gone down considerably in all Western nations, sometimes by more than 50%. In Germany, rates of car theft have already started to fall by almost 50% in 1961. This drop tracked federal legislation that made high-quality steering column locks mandatory in all cars. Car thefts dropped already the same year (Mayhew, 1992). In the USA and Britain similar legislation was passed 10 years later but limited to the fitting of steering column locks in newly sold cars. As was to be expected, the impact of these regulations was much more delayed than the German. In Britain it took almost 10 years before over 80% of cars were fitted with steering column locks. It was indeed around that time that rates of car theft per 100 owners started to stabilize. In the USA the impact of the new regulation came faster, which appears related to a faster renewal of the vehicle population than in Britain. The critical penetration rate of 80% was reached earlier and car thefts rates started to fall accordingly much sooner. Studies into the impact of state-of-the-art security measures against car theft have been conducted in many countries in more recent years, often using data from victimization surveys (Farrell et al., 2011a). Electronic immobilizers were found to be the most effective to prevent theft of cars. In Australia, the USA, Europe, and Canada the falls in car theft have tracked increases in the penetration rate of anti-car theft security among cars (Fujita and Maxfield, 2012). Electronic immobilizers were made mandatory in 1998 for all newly sold cars within the European Union. Within 10 years after the regulation took effect, it had reduced car thefts by 70% in the Netherlands and by 80% in Britain, according to the analyses of Van Ours and Vollaard (2012). Across the Western world improved car security has substantially reduced nonprofessional car theft (joyriding) (Van Dijk, 2012). Over the last years the introduction of parts marking seems to have driven down professional car theft as well in both the USA and Taiwan.

The second example of security-driven falls in crime is household burglary. In the Netherlands the installment of basic household security measures has been actively promoted by the government since the mid-1980s. In 1999, basic household security was included in the Building Regulations and since then such security is mandatory for all newly built houses. Vollaard and Van Ours (2011) analyzed results of the Dutch national victimization surveys to determine the impact of the new building regulations upon burglary victimization rates of owners of newly built and older houses. Their analysis shows that risks to be burgled of houses built after 1999 are reduced by 50%. According to the authors the new building regulations had been responsible for almost a fifth of the total drop in burglaries in the Netherlands in recent years.

Western countries show considerable variation in levels of household security. Levels of home security are by far the highest in the Netherlands and the UK and the lowest in Estonia, Switzerland, and Denmark. The repeat of the ICVS in 2010 in eight Western countries allows a test of the hypothesis that trends in burglary victimization between 2004 and 2010 are related to the level of security in 2004. The results revealed that among the eight participating countries such relationship is indeed in evidence (Van Dijk and Vollaard, 2012; Van Dijk, 2012). Burglary rates dropped in the Netherlands and the UK and went up in Denmark and Estonia and remained stable in the four countries with medium levels of security. When measures of home security are added up, the correlation between level of home security in 2004 and the trends in burglary victimization between 2005 and 2010 is near perfect. The fact that the UK and the Netherlands resemble Denmark and Switzerland on key economic and social indicators makes the relationship the more telling.

The links between improved security and drops in car theft and burglary suggest that security has acted as the main driver of the universal drops in property crime in a more general sense. If levels of crime have been propelled, as supposed by Felson and others, by expanding pools of suitable targets of crime during the postwar economic booms, improved security might eventually have driven crime rates down (Farrell et al., 2011b). Important examples of improved security across the board are the huge increases in private security guards and alarm centers. In 'Western' countries private security guards now outnumber police officers (Van Steden and Sarre, 2007; de Waard, Berghuis, 2012). But such 'responsive securitization' is not limited to human surveillance by security guards. Measures to prevent crime have become ubiquitous in all corners of modern society. Harnessing new technology, security provisions have been built into homes, cars, stores and parking lots, public transport and public/social housing, schools and hospitals, offices and other work places, entertainment venues and sports stadiums, airports and seaports, and to warehouses and transportation terminals (Clarke and Newman, 2006). Other specific examples of effective security are situational measures against robberies of post offices and banks (Laycock, 2001). The security hypothesis is especially pertinent to understanding emerging trends in new forms of e-fraud. Relatively high levels of identity theft in the USA, for example, are explained by levels of mandatory security below those on the European continent (Van der Meulen, 2011).

As security, crime prevention, and criminal justice reach sufficient levels, the costs of offending will increase and crime rates are likely to start falling. Increased affluence leads to a 'crime harvest' in the medium term that can last for decades. Subsequently measures are put in place by producers of vulnerable products or potential victims to counter increased losses from crime, and crime rates begin to stabilize at a lower level and then to fall.

Whether the current security-driven international drops in property crime will be sustainable in future years remains to be seen. Now that levels of many types of property crime have been more than halved, the motivation to apply security

measures may wane and opportunities of burglary, theft, and fraud may widen again. New products and services may once again ample offer opportunities for the commission of profitable crimes. In the USA the first signs of a new upswing in rates of property crimes have been observed through the national victimization surveys. In 2012, victimization by both violent and property crime went up considerably for the second consecutive year (Langton et al., 2013). A new crime epidemic might be in the making, posing a challenge to both governments and potential victims.

Property: Legal Aspects

Peter S Menell, University of California, Berkeley, CA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Property encompasses the governance of resources – real property (land), natural resources, and personal property (chattels and intangibles, including copyrights, patents, stocks, claims of right). Private property finds support in Locke's labor theory, as well as libertarian, utilitarian, and personhood philosophical traditions. Distributive justice, civic republicanism, and ecological theories take more qualified stances on the protection of private property, while Marxist ideology rejects private property as a vestige of exploitation and alienation of the worker class. Modern conceptions of property trace their roots to Blackstone's inviolate, unified bundle of rights (see following). As societies moved beyond agrarian modes of production, and as legal relations evolved from status to contract, the bundle of rights gradually came to be seen as malleable instruments to be tailored by legislatures, courts, government agencies, and markets. By the twentieth century, zoning and other governmental regulations significantly qualified the rights of property owners, and scholars developed frameworks for analyzing the economic, distributive, and other moral implications of different systems of resource governance. A new conception of property integrating the many institutional structures governing resources, the cultural contingency of governance regimes, and the dynamism of governance institutions has emerged. This broader framework provides the basis for tackling the new frontiers of resource governance.

Property encompasses the governance of resources – real property (land), natural resources, and personal property (chattels and intangibles, including copyrights, patents, stocks, and claims of right). Natural law theory, beginning with Aristotle and perhaps best articulated in the writings of John Locke (1698), posits that "life, liberty, and property" exist naturally as a matter of fundamental principles of justice, irrespective of the state. Echoing Locke's formulation, the United States Constitution provides that a person may not "be deprived of life, liberty, or property, without due process of law; nor shall private property be taken for public use, without just compensation." By contrast, legal positivists, such as Jeremy Bentham (1789), assert that property rights arise only to the extent that they are formally recognized by the state: "Property and law are born together, and die together. Before laws were made there was no property; take away laws, and property ceases." Both views give content to what we understand as property. Legal positivism captures the practical reality that legislatures and courts define property rights in most societies, and that property rights have practical meaning only to the extent that they are enforceable. Nonetheless, natural law (and other philosophical frameworks) informs the content of property rules by providing the justification for state-created rights.

Philosophical Justifications for and Critiques of Private Property Rights

Waldron (1988) suggests that property is best viewed as a "system of rules governing access to and control of material resources." These rules are often characterized as a bundle of rights – in the case of land, the rights to possess (or occupy), to exclude, to use, to transfer, to enjoy fruits, and to alter or destroy – that can be allocated in different ways. Particular bundles represent different conceptions of property, which derive from one or more philosophical justifications.

Labor Theory

John Locke (1698) offered a strong natural rights justification for private property, which remains a central pillar of property theory today. Beginning with the proposition that all humans possess property in their own 'person,' Locke argued that

> [t]he 'labour' of his body and the 'work' of his hands, we may say, are properly his. Whatsoever, then, he removes out of the stat[e] that Nature hath provided and left it in, he hath mixed his labor with it and joined to it something th[a]t is hi[s] own and thereby makes it his property. It being by him removed from the common state Nature placed it in, it hath by this labour something annexed to it that excludes the common right of other men. For this 'labour' being the unquestionable property of the labourer, no man but he can have a right to what that is once joined to, at least where there is enough and as good left in common for others.

Locke's theory is widely viewed as justifying first possession as a basis for acquiring property rights (Rose, 1985; Epstein, 1979). While useful as a basis for establishing rights in land and raw materials in a world of abundant unclaimed resources, Locke's theory significantly qualifies the laborer's claim in a world of scarcity – requiring 'enough and as good left in common for others.' Waldron (1988), Rose (1987), Ryan (1984), Becker (1977), and Schlatter (1951) elaborate and critique Locke's justification for private property rights.

Libertarianism

Drawing upon Lockean principles, libertarians emphasize individual freedom to control and alienate their private property. Nozick (1974) asserts that the state should play no role in distributing or redistributing property acquired properly, apart from respecting the voluntary transfers of property owners. Epstein (1985) argues for a broad interpretation of the government's obligation to compensate owners of private

property for regulation and other governmental decisions interfering with private property rights.

Utilitarianism

First articulated by Jeremy Bentham (1789), utilitarianism judges the allocation of resources and the design of governance institutions on the basis of the utility or individual satisfaction that they produce. In applying this theory to property rights, utilitarian scholars have focused principally upon the inefficiency that can result from incomplete or shared resource ownership and external effects of property use (such as pollution) on neighboring parcels. In a classic work, Hardin (1968) describes the "tragedy of the commons," whereby unregulated access to a common pasture (or any other common resource such as air, water, or roads) results in overuse. Hardin suggested that private property or government regulation is needed to govern the commons.

Yet private ownership can produce other pathologies. Heller (1998, 2008) explains that excessive fragmentation of property interests can produce a "tragedy of the anti-commons," whereby the cost of determining rights and negotiation paralyze resource use and development. Merrill and Smith (2000) and Smith (2012) explain how standardization and modularity of property units can promote efficient property development and use and ameliorate anti-commons problems.

Menell and Meurer (2013) show that the claiming of resources – such as newly discovered land, mineral rights, or most saliently today, intellectual resources (e.g., patents) – can produce 'notice externalities.' In economic parlance, an externality arises when an actor imposes costs on other parties – for example, by discharging pollutants that adversely affect a downstream fishery. A notice externality arises when property claimants obscure their claims – for example, by seeking patent claims with amorphous boundaries or hiding their identities. This raises the costs of those seeking to develop 'neighboring' properties (or in the case of patents, 'neighboring' technologies), who must expend additional resources on surveying (or in the case of patents, search, and opinion letters) and bear the risk and cost of later disputes about encroachment or infringement. Once their investments are sunk, the property claimant can pounce opportunistically, with the object of holding up the neighbor's investment. Had the property claim been clear from the outset, the neighbor could have confronted the issue prior to sinking the investment.

Economists generally prefer private property institutions (Posner, 1998), although the efficacy of private property depends critically upon the costs of creating, monitoring, and enforcing such rights (Smith, 2002; Lueck, 1995; Ellickson, 1993; Anderson and Hill, 1975; Demsetz, 1967). Government regulation often entails two costs: (1) direct costs to comply with the regulations imposed; and (2) influence costs attributable to rent-seeking (or lobbying) – ex ante efforts to secure economic advantage through favorable government decisions by those interests affected by regulation. Although private property regimes often ameliorate the tragedy of the commons, shared governance institutions including informal social norms can maximize utility in a range of circumstances depending upon the cohesion and history of the community affected and the nature of the resources in question (Libecap, 1994; Ellickson, 1991; Ostrom, 1990; Rose, 1986).

Personhood

The personhood justification for private property, derived from Kant's Philosophy of Law and Hegel's Philosophy of Right, has been elaborated in modern legal discourse in the work of Radin (1982, 1993). "The premise underlying the personhood perspective is that to achieve proper development – to be a person – an individual needs some control over resources in the external environment. The necessary assurances of control take the form of property rights" (Radin, 1982). The personhood justification for private property emphasizes the extent to which property is personal as opposed to fungible: the justification is strongest where an object or idea is closely intertwined with an individual's personal identity and weakest where the 'thing' is valued by the individual at its market worth. The personhood justification for private property is limited and highly subjective (Schnably, 1993).

Distributive Justice

Theories of distributive justice seek to allocate society's resources on the basis of just principles. The process of determining such principles is the focus of considerable debate. Many theories incorporate utilitarian and Lockean principles. In perhaps, the most influential work on distributive justice of the past century, Rawls (1971) offers an 'ideal contractarian' theory of distributive shares in which a just allocation of benefits and burdens of social life is determined by what rational persons would choose from behind a 'veil of ignorance,' which prevents them from knowing what abilities, desires, parentage, or social stratum they would occupy. Rawls concludes that people behind such a veil would adopt what he calls the 'difference principle': 'primary goods' – not only wealth, income, and opportunity, but also bases of self-respect – would be distributed to the maximal advantage of a representative member of the least advantaged social class. Rawls (1993) emphasizes that the difference principle does not call for simple egalitarianism but rather measures to assure that "the basic needs of all citizens can be met so that they can take part in political and social life."

Civic Republicanism

Republicanism rejects the view that individuals are wholly autonomous and that the public interest is just the aggregation of individual preferences. Republicanism stresses civic virtue and the role of participation in public discourse as essential to the realization of the common good. Civic republicanism relies upon the propertied independence of its citizens. Such ownership of capital affords citizens the competence to engage in meaningful discourse and protects against the subversion of democracy by a wealthy oligarchy or an aggressive state (Simon, 1991).

Marxist Theory

Karl Marx viewed human history as an evolutionary process of class struggle leading, ultimately, to a classless society

(communism) in which the state will wither away. In the capitalist phase of this evolution, private property provides the basis for the most important social relation: ownership of the means of production. According to Marx, the class owning the means of production (bourgeoisie) acquires the property (capacity to work) of the labor class (proletariat) through the employment relation, thereby obtaining exclusive control of and hence power over the worker class. Such subordination, exploitation, and alienation sow the seeds of revolution, leading to the establishment of a proletarian dictatorship, socialism (productive resources owned by workers through participatory institutions), and eventually communism, a classless society without exploitation or inequalities in which property in land and rights of inheritance are abolished (Marx and Engels, 1848).

Ecological Theories

As understanding of the connections between technology, land development, and the environment has deepened, many environmental scholars have increasingly viewed private property rights more skeptically (Sax, 1983). Traditional reformist theories – which are anthropocentric in nature and draw heavily upon utilitarian and other traditional philosophical frameworks – favor internalization of the adverse impacts of development (Menell and Stewart, 1994; Ellickson, 1977, 1973). Building upon Leopold's (1949) call for a land ethic that seeks to "preserve the integrity, stability, and beauty to the biotic community," Freyfogle (1996), Sprankling (1996), and Sax (1993) propose a shift away from private property toward greater regulation and coordination of land and natural resource development. At the other extreme, Anderson and Leal (1991), drawing upon property rights and public choice literatures, advocate complete reliance on private property and free market principles as the best institutional choice to address substantially all environmental problems. Menell (1992) highlights the institutional limitations of both extremes and urges careful attention to the strengths and limitations of the broad spectrum of institutional alternatives in governing resources.

Pluralist and Hybrid Theories of Property Rights

The insights of the many philosophical perspectives have led some scholars to synthesize multiple strands into new and comprehensive theories for justifying and evaluating property. Munzer (1990), for example, constructs a theory of property built upon principles of utility and efficiency, justice and equality, and rewards based on labor. Simon (1991) synthesizes civic republicanism and socialism to advocate an intermediate form of property emphasizing enterprise and community-based democracy (cf. Hansmann, 1996), offering a utilitarian explanation for worker-owned and managed firms and organizations.

The Emergence of Private Property Rights

Although no single philosophical theory provides a complete explanation for private property rights, utilitarianism has emerged as the dominant framework for understanding property rights systems in capitalist economies. In a seminal article, Demsetz (1967) posited that private property regimes develop to internalize externalities. As the benefits of internalizing externalities rise (e.g., where a common resource becomes more valuable) or the cost of internalizing externalities fall (e.g., as technology reduces the costs of fencing or monitoring property rights), private property systems emerge to promote efficient management of the resource. As support for this thesis, Demsetz cites anthropological evidence from the Americas following the arrival of the Europeans and the origins of the fur trade. The fur trade, by spurring the hunting of beavers, created the need for property rules to internalize and minimize the effects of resource exploitation. In response, Native Americans established private hunting territories.

Demsetz's theory explains the emergence of private property institutions across a broad range of contexts, including air (sulfur oxide emissions in the United States), water allocation, fishing, the telecommunications spectrum, wetlands, roads (tolls), trademarks (causes of action for diluting famous marks), and publicity (commercial exploitation of a person's image, likeness, or voice). Nonetheless, by focusing exclusively upon private property institutions, Demsetz's theory overlooks much of the richness of property institutions and the complex social processes that affect their evolution. Smith (2002), Libecap (1994), Ostrom (1990), Ellickson (1991), Rose (1986), and others explore the broad spectrum of property institutions lying between the poles of pure private property and the commons, where informal and shared governance emerge and succeed in allocating resources. The emergence and nature of property rights in a given place and time are also likely to reflect aspects of that society's political economy, including features of the legislative process and of government agencies that administer property rights (Buchanan and Tullock, 1962). Interest groups tend to form in those areas where government policies create concentrated benefits or impose concentrated costs (Olson, 1965). Laws and agencies creating or affecting property rights (e.g., through regulation) attract substantial rent-seeking activity. Thus, the design of property regimes often reflects political, as well as economic and social, considerations.

Evolution of Jurisprudential and Analytical Conceptions of Property

Although property rights are as old as human civilization, the modern jurisprudential conception of property traces its roots to the agrarian and early mercantilist economies that developed during the decline of feudalism. Sir William Blackstone (1765), author of the first widely accepted legal treatise on English law, regarded property as an absolute right

> which consists in the free use, enjoyment, and disposal of all acquisitions, without any control or diminution, save only by the laws of the land …

> So great moreover is the regard of the law for private property, that it will not authorize the least violation of it; no, not even for the general good of the whole community … .

Although some have questioned Blackstone's rigor and cogency (Burns, 1985), few doubt his influence upon the jurisprudence of property in England and America. Maine (1861) reinforced the superiority of private property institutions through his historical account of the progress of civilization from primitive forms of shared ownership among kinship groups (status) to individual ownership and alienability of property interests (contract).

The industrial revolution and the shift from an agrarian economy to urban and other community structures changed the ways in which land and other resources were owned and exploited. The desire to restrict land through contract pushed courts to liberalize constraints on non-possessory interests, presaging the disintegration of the unitary bundle of sticks (French, 1982; American Law Institute, 1936). Property came to be seen increasingly as a malleable concept that could be tailored to serve utilitarian purposes.

In the early twentieth century, Hohfeld (1913) developed a detailed descriptive framework for capturing the richness of legal rights, reconceptualizing property as *relationships* among people relative to things. Recognizing four primary legal entitlements – rights, privileges, powers, and immunities – Hohfeld postulated four basic legal relations ('correlatives'): 'right–duty,' 'privilege–absence of right,' 'power–liability,' and 'immunity–disability.' Hohfeld provided the vocabulary and structure for representing the complexity of property relations – bundles of rights (and relations) – as well as the conceptual menu from which legislatures and courts could craft property rights.

Blackstone's conception of property as an inviolate, unified bundle of rights came under increasing assault with the proliferation of zoning and other public land use controls upon private property rights and the expansion of the role of government at all levels following the New Deal in the United States. Property rights, like much of the law governing legal relations, came increasingly within the purview of political institutions, and accordingly gave way to the instrumentalist (utilitarian) nature of politics.

In a seminal article, Coase (1960) developed a new, instrumentalist framework for analyzing property rights. In much the way that a frictionless surface enables physicists to isolate and study the laws of physics, Coase hypothesized a world of zero transaction costs (costless bargaining and enforcement of agreements), which provided valuable insights into the interplay of legal and market institutions. Coase demonstrated that in a world of costless transactions, an efficient allocation of resources will result regardless of how property rights are initially allocated. The desire of conflicting property owners to maximize their joint profit will lead them to bargain to an efficient allocation of resources. The initial allocation of entitlements will affect the distribution of wealth, but not the total level of wealth.

As with the frictionless surface, Coase recognized that costless transactions do not exist in the real world. His article fueled a deluge of scholarship exploring the implications of costly transactions for the allocation and design of property rights. Building upon Coase's construct, Calabresi and Melamed (1972) developed a framework that divides the analysis of property rights into two inquiries: (1) how should property rights be allocated; and (2) how should such entitlements be enforced – by a property rule (enabling property owners to enjoin interference with their entitlement and requiring consent for violation or transfer of the entitlement), a liability rule (allowing property owners court-determined damages for invasion of their property right, as in the case of eminent domain), or by a rule of inalienability (preventing transfer of a property right, as with prohibitions on the sale of body parts).

Calabresi and Melamed propose that entitlements and enforcement rules be based on economic efficiency, distributional goals, and other considerations of justice. Where transactions are costly, entitlements should be allocated so that the party who is best able to minimize harm (the least cost avoider) bears responsibility for the harm in order to promote economic efficiency. With regard to the enforcement of entitlements, Calabresi and Melamed demonstrate that the use of liability rules can minimize the costs of making an erroneous decision about the allocation of entitlements where transactions are costly. Subsequent scholars have refined and extended the framework and applied it in a range of contexts (Symposium, 1997; Kaplow and Shavell, 1996; Merges, 1996; Radin, 1996; Krier and Schwab, 1995; Rose-Ackerman, 1985; Polinsky, 1980; Ellickson, 1977, 1973).

In a provocative essay published in the early 1980s, Grey (1980) argued that the field of property "ceases to be an important category in legal and political theory" as a result of the 'disintegration' of the conception of property. In his view, the dividing of property ownership into a 'bundle of rights' and the development of differing conceptions of property across disciplines has 'fragmented' property theory 'into a set of discontinuous usages.' Numerous scholars have questioned Grey's claims on a range of bases (Merrill and Smith, 2001 (contending that it is essential to view the institution of property as an *in rem* ('thing') concept), Smith, 2012; Epstein, 2010; Munzer, 1990), yet the observation that provided the point of departure for Grey's essay, the 'disintegration' of property, resonates today (Menell, 2011; Dwyer and Menell, 1998). Property has lost the simplicity of Blackstone's conception – unitary, exclusive, and omnipotent control – but a new conception of property integrating the many institutional structures governing resources, the cultural contingency of governance regimes, and the dynamism of governance institutions has emerged.

Property as a Triadic Relation

Dwyer and Menell (1998) present property as a dynamic system comprising three components: resources, institutions, and culture. Resources may be governed by background legal institutions (such as common law rules, or in civil law regimes, codes), social norms, markets (contractual agreements supported by the background legal institutions), political institutions (e.g., zoning), or some combination thereof. At any point in time, the mix of governance rules and institutions reflects the nature of the resources governed and the society or culture (knowledge, values, cohesion, technology) in which the resources are situated. Thus, in smaller, more cohesive social settings, we observe greater use of social norms or shared governance structures, whereas the

same resources tend to be governed through formal private property institutions in larger, more heterogeneous communities. The triadic framework captures the economic and cultural dependency of resource governance as well as the diversity and richness of property regimes.

The triadic conception of property also incorporates the dynamic nature of resource governance. As reflected in Figure 1, changes in the society (such as the value attributed to the protection of endangered species or technological advances reducing the costs of monitoring private property rights in particular resources) generate changes in the design and mix of governance institutions. Such changes, by affecting the resource base, can generate further reactions within the overall system through various feedback mechanisms. The system can also be affected by external shocks, such as changes in the larger political atmosphere. Demsetz's (1967) positive account represents a special case of this dynamic process, but the triadic relation generalizes the dynamism of institutional evolution to account for a broader mix of governance institutions (see also Smith, 2002).

Figure 1 Property.

New Frontiers

Notwithstanding the settlement of substantially all significant land masses on the planet, the frontiers of property continue to expand and evolve. Among the most important resources in today's economy are intangibles – ideas, genetic code, cyberspace, telecommunication spectrum (Merges et al., 2012). The Internet has significantly expanded opportunities to distribute expressive works, but has also threatened the ability of copyright owners to control their works (Menell, 2002, 2011). This new medium has reshaped perceptions about rights to reproduce and distribute expressive works. Advances in bioscience have spawned disputes over rights and control of human genetic code, cell lines, and indigenous plants. And even in the more conventional realm of land management, increasing pressures on natural resources, greater knowledge of ecosystem effects, and changes in attitudes toward the environment continue to alter the balance among private property rights, public ownership, and regulation (Dwyer and Menell, 1998; Menell and Stewart, 1994; Rieser, 1997). Public rights in artistic treasures, historical documents, architectural works, archeological discoveries, and scholarly research present a further set of challenges for a system of governance built significantly upon a foundation of private property rights (Sax, 1999). Just as the advent of rights in government benefits expanded our conception of property four decades ago (Reich, 1964), advances in technology and changing social values continue to expand and alter our conception of property (Rose, 1998).

Property: Legal Aspects of Intergenerational Transmission

Ronald Chester, New England School of Law, Boston, MA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Inheritance is a legal and customary institution that not only is universal but also has been so for centuries. This article discusses both historical and current differences in the transmission of wealth between generations, as well as the relative importance of these differences. It also analyzes future trends in the transmission of property between generations and considers possible changes to the current legal regimes.

Property is transmitted at death by succession, will, will substitute, or a combination of these methods. While the right to transmit property by will is seen by some as a natural right, more often it is viewed as a positivist creation of law for the convenience of society. One of the chief issues in intergenerational wealth transmission has long been the extent to which a decedent could, by use of a will, vary in customary or legal succession patterns protecting the family. The ability to change these succession patterns by will has increased, particularly among English-speaking peoples, as societies have evolved from feudalism to modern free-market capitalism. The Anglo-American concept of a trust, which separates legal from equitable title and can provide managed income for a beneficiary without ever-vesting full title in that individual, complements, or may even supplant, the will in transmitting property between generations.

The attempted abolition of inheritance by the Bolsheviks in 1918 failed in the Soviet Union and was never attempted by the Communist Chinese. Both nations today have inheritance laws that generally mimic those of the civil law systems of Western Europe, where family protection through forced-succession laws tends to limit testamentary freedom. Allowing large amounts of capital to pass between generations without significant taxation is problematic for countries (like the United States) that profess a belief in equal opportunity. Continental nations are generally more active than the United States in taxing such wealth. Such countries as France, Spain, and Germany limit testator freedom not only in this way but also by demanding the family protection mentioned here. Whether the United States will join these and other countries in their approach to intergenerational wealth transfer or continue to protect the rights of individual decedents over the needs both of blood relatives and of society is an open question as the twenty-first century unfolds.

Wills and Succession throughout History

Property exists essentially in two forms: movable (including intangible) and immovable (land). An heir's right of succession to property by law or custom is an ancient and powerful right rooted in kinship ties. For example, early European feudal societies allowed family members to share that portion of the land vacated by a kinsman's death (see Chester, 1982). By the twelfth century in England and in many parts of Western Europe, lands were not partitioned but descended to the eldest son of the landowner under the concept of primogeniture.

The right of a beneficiary to take property under a will is dependent on the legal power or right of the decedent to transmit this property at death to that beneficiary. This right was recognized relatively recently in Western thought and has often been regarded, at least by the positivist tradition, as having been created for society's convenience. Natural rights advocates, by contrast, might consider the right to bequeath an aboriginal attribute of property itself that may not be subject to curtailment (see, e.g., Ascher, 2011; Chester, 1998b, 2007).

In Western society, the legitimization of the right of bequest symbolized the shift from feudal to individualistic conceptions of property. Unknown to the early law of Greece, India, Egypt, Babylon, and Israel, the will was by no means a universal institution. The testamentary conception built upon by Europeans had its roots in Roman law and was resurrected after feudalism by ecclesiastical courts applying Romano-canonical law (see McMurray, 1919).

In England, the customary right of testamentary disposition was recognized in very early times, but land – the primary source of wealth – could not be willed until after the Norman invasion and the establishment of feudal tenures. Finally, in 1540, the Statute of Wills declared the right of an individual to leave real property to whomever the individual pleased by means of a duly executed will. This statute confirmed a customary right long recognized for personal property (Chester, 1982).

Once established, the right of an individual to leave property outside the family had to be reined in to protect certain family members from disinheritance. For example, in England, primogeniture protected the eldest sons of landed decedents until well into the nineteenth century. Common law rights of dower and curtesy for surviving wives and husbands provided them with interests in the land of the decedent at decedent's death (see Chester, 1982). 'Dower' refers to the portion to which a surviving wife is entitled, while 'curtesy' refers to what a surviving husband may claim.

Even though a married English woman of the sixteenth, seventeenth, and eighteenth centuries could not will property (except, possibly, with her husband's consent) or own it in her own name, it could descend through her. However, married women's assets were protected to some extent by courts of equity by means of trusts and other devices, especially toward the end of that period.

Children who were omitted from wills were not protected directly, except those benefiting under primogeniture. However, the wills of their parents were strictly scrutinized to ensure that these children had not been left out unintentionally. One English rule derived from Roman law even stated that to cut off an heir 'without a shilling' raised a presumption that the testator was legally incompetent to make a will. Thus, even in England, the family's right to inherit property was protected not only when the decedent died without a will (intestate) but also to some extent when the decedent did leave such a will (see Chester, 1982).

The entrenchment of the right of testation in England was associated with the movement from feudalism, with its emphasis on family and kinship, to free-market capitalism, with its emphasis on the individual. By the mid-nineteenth century, the adult, male, Anglo-American owner of both realty and movable property had nearly unlimited power of testamentary disposition. In contrast, countries such as France, Spain, and Germany on the European continent made the move to capitalism with a right of testation that, even when recognized, was much more sharply curtailed than in Anglo-America by the requirement of fixed shares for the surviving spouse and children.

In the eighteenth and nineteenth centuries, the principal difference between the Continental and Anglo-American systems of succession was the different attitude each displayed toward the right of family members to succeed to the decedent's property. Although the Spanish principle of forced succession appeared in theory to be a significant curb on the Anglo-American concept of testamentary freedom, in practice the differences were not so marked. This reality stems from two separate phenomena: (1) in the majority of instances, free testamentary power among the Anglo-Americans was exercised in favor of those who would be forced heirs under a mandatory system such as that in Spain; and (2) even where testamentary power appears absolutely undiluted, far more people die without wills than with them, resulting in the passage of their property to those who, under Spanish law, for example, would be designated forced heirs (see McKnight, 1996).

Spanish lawyers of the eighteenth and nineteenth centuries were trained in the Germanic tradition, which accepted only an extremely narrow testamentary power. Thus, while Anglo-American lawyers thought of both testate and intestate successions, the basic distinction for the Spanish was between those who were forced heirs and those who were not.

What is more, married women in the Spanish system not only had a much more extensive right to property than did those in Anglo-America, but also had will-making power, which married women did not have in Anglo-America. Married American women, for example, did not gain the power of will–making until the passage of the Married Women's Property Acts of the late nineteenth century.

In Spain, the surviving spouse was also entitled to half of the gains of the marriage under what is today termed 'the community property system.' Most of the property that was the decedent's alone passed to descendant forced heirs, despite any contrary testamentary provisions, and if there were no descendants, ascendants took as forced heirs, although in smaller shares than descendants. If the decedent died without a will, the estate passed to the forced heirs, or, if none, to other heirs as dictated by law (see McKnight, 1996).

French law also maintained forced heirship under the concept of legitim. During the French Revolution, this concept was viewed as a means of eliminating the feudal principle of primogeniture in order to break up feudal estates. There was some relaxation in the strict adherence to forced heirship by the time of the Napoleonic Code, which announced the general French view of succession that is held even today. Under the Code, half of the testator's estate (after marital property has been distributed to the surviving spouse) was freely disposable if there was one child, one-third if there were two children, and one-fourth if there were three or more children (see McKnight, 1996).

In general, since the early fifteenth century, the difference between Continental and Anglo-American views of succession, seen most strikingly in the Hispanic tradition, is that the Spanish adhered to the traditional Germanic tribal concept of familial right to property, whereas the Anglo-Americans took an individualistic view of who should succeed to the decedent's property (see McKnight, 1996). By the mid-nineteenth century, this English individualistic notion had triumphed throughout the United States, with the exception of Louisiana, which followed the French law of legitim. The Anglo-American system was, however, tempered by the concept of community property in states with a Spanish tradition and by dower and curtesy (see section Wills and Succession throughout History) in the others. Community property rules gave each spouse an immediate half interest in any property acquired during the marriage, while dower provided a surviving wife with a life interest in one-third of her dead husband's real property, and curtesy gave a surviving husband a life interest in all of the wife's real property.

Trusts

A particularly ingenious device that could be used for the intergenerational transfer of wealth was developed in Anglo-American courts of equity. Called the trust, it has sometimes been copied in other legal systems, such as that of modern Japan (see *International Law Digests*, 1999). This form of property holding enabled the decedent to pass legal title to a third party who held the property for the benefit of its intended beneficiary. This third-party trustee was subject to the equitable interest of the beneficiary, who generally received the income from the property for a period of time up to life. At the end of the designated period, the equitable title of that beneficiary would cease, transferring absolute ownership to that beneficiary or another chosen by the decedent.

The temporary division of legal and equitable title to property in trust allows, among other things, professional management of trust property assets. It also allows decedents to delay the actual vesting of full title to the property for a period of time up to and including a generation or more, during which period a beneficiary may receive a managed stream of income. Trusts in the United States that pay income to a decedent's children during their lives, and upon their deaths pay the principal to the grandchildren, are called

generation-skipping trusts. Estate tax advantages of these trusts (achieved because the children never received full title) were cut back by the Tax Reform Act of 1986 and subsequent amendments (which imposed a generation-skipping transfer tax; see Johnson and Eller, 1998; Dukeminier et al., 2009).

Wills and Succession among Nations in the Twentieth Century

The United States took freedom of testation one step further than did England and the countries of the British Commonwealth. While, in varying degrees, these nations developed flexible systems of family maintenance to protect surviving spouses and children (at least adult, competent children) from disinheritance, the United States maintained the right of the testator to disinherit his or her children completely, even those children who were minors and/or had need. Thus, while surviving spouses in the United States are protected either by the elective share (in 'common law' states following the English tradition) or by community property laws (in those states following the Spanish tradition), the protection of surviving children theoretically is left to the whims of the parent.

Although this disparity has been attacked, it has also been noted that flexible concepts such as lack of testator competence, undue influence, and 'unintentionally' omitted children indirectly protect surviving children to some extent in most 'common law' states (see Chester, 1997, 1998a).

That the United States's focus on the individual rights of the decedent, even to the exclusion of children and other descendants, is unusual can also be seen by examining the systems of the Soviet Union (before its dissolution) and China. Traditionally, the Soviet law of inheritance did not differ substantially from that of the civil law countries of Western Europe (see Dukeminier et al., 2009). Although the Bolsheviks attempted to change this during the early years of their takeover of power, this attempt failed. Nearly unique in the modern history of humankind, a 1918 Soviet Union law read: "inheritance, testate and intestate, is abolished. Upon the death of the owner his property (moveable and immovable) becomes the property of [the state]" (1 Sob. Uzak., RSFSR, No. 34, item 456, 26 April 1918). This attempt to abolish inheritance proved so unpopular with the people that inheritance was reestablished within four years (see Foster-Simons, 1985).

At present, inheritance law in Russia and the republics of the former Soviet Union generally follows the civil law views of Western Europe. In this way, it is similar to the law in modern China (see Dukeminier et al., 2009). In that country, if first-order heirs (spouse, children, and parents) inherit, then no second-order heirs (brothers, sisters, and grandparents) will inherit. Following a kind of community property system, all property in China acquired during marriage is joint property, unless the marital partners have executed a contract to the contrary (see *International Law Digests*, 1999). Since much of China is still rural and nonindustrial, custom plays an important part in the actual distribution of estates (see Foster-Simons, 1985), just as it does, for example, in tribal Africa. This distribution depends partly on the law and the terms of any will and partly on the social and economic facts relevant to the intestate, or the testator and his or her heirs (see *International Law Digests*, 1999).

Free Testation and Capitalism

It is tempting to view the relatively free testation of the United States as coincident with that country's status as the exemplar of capitalism. Except for the elective share provided for surviving spouses (e.g., one-third of the estate), testation in the United States is predicated on protecting the free will of the testator. While England and the Commonwealth countries are certainly capitalistic, their laws show, on the whole, more of a socialist's regard for protection of society (and family) than do those of the United States. While family protection is achieved in these countries by reposing a great deal of discretion in probate judges to ensure family maintenance (as distinguished from the use of fixed shares in the Continental system), this still provides a strong check on the whims of the testator. The governmental intrusion into testation is, of course, even more pronounced on the Continent, where fixed shares for the family are the norm.

In its 1987 decision in *Hodel v. Irving* (481 US 704, 1987), the US Supreme Court even seemed ready to protect *constitutionally* the right of an individual to transmit property at death in any manner that he or she might choose. While that decision has been criticized and not extended beyond its facts (which involved government confiscation of noneconomic land parcels descending at the death of American Indians), it symbolizes the United States' fierce protection of individualism, even after the individual's death (Chester, 1995, 1998b, 2007). Interestingly, the occasion for that decision was the government's attempt to save Indians from the disastrous economic effects of the Anglo-American individual property system that had been forced on the various tribes. Without imposition of the notion of individually held property in the first place, functioning Indian tribes, much like the tribes in sub-Saharan Africa, might have continued to treat property, which is chiefly in the form of land, as a family (and, by extension, community) asset that was never the individual's to transmit at death in the first place.

Implications of Inheritance and Taxation Policy for Equal Opportunity and the Distribution of Wealth

Allowing large amounts of capital to pass between generations without significant taxation is problematic for countries, such as the United States, that profess a belief in equal opportunity. Taxation of estates and gifts is widely seen as an intrusion on the freedom to transmit property at death – a freedom that Americans particularly seem to cherish. While the American estate and gift tax has high nominal rates, its high exemption levels (as of this writing, $5 000 000 per decedent, $10 000 000 per married couple, plus cost-of-living adjustments) and numerous loopholes, including a deduction of up to 100% for all property left to a surviving spouse, may make it in effect a 'voluntary tax' (see Cooper, 1979).

Countries such as France and Spain have both an inheritance tax and an annual tax on accumulated wealth. Perhaps not coincidentally, these countries do not have so strong a tradition as does the United States of allowing testators to do almost anything they want to do with their money at death.

Commentators (e.g., see Ascher, 1990, 2011; Chester, 1976, 1982, 1998a, 1998b, 2007) have noted that the policies of free wealth transmission and equality of opportunity coexist very awkwardly in the United States. Although legal systems cannot control differences in natural ability or the luck of being born into a family that values, for example, culture and education, they *can* curb that form of luck represented by inheritance. If equality of opportunity is truly a key goal, then children fortunate enough to have been reared and educated by wealthy parents need not be allowed the additional luck of freely inheriting their parents' property. Strong and effective taxation of inheritances would contribute significantly to this goal of equal opportunity.

Whatever the logic of this point of view, in the United States there appears to be little public support for more effective taxation on postmortem (or even lifetime) transmission of wealth to heirs. In fact, at the beginning of this twenty-first century, bills in Congress relating to the estate tax generally call for its softening or its abolition. Those supporting such bills argue that low or nonexistent taxation of inherited wealth is good for the economy because it preserves large blocks of investment capital in private rather than government hands. However, it might also be said that untrammeled inheritance saps the initiative both of those who receive it and of those who cannot possibly compete on equal terms with those who do (see Chester, 1976, 1982).

The Future

In looking toward the future of intergenerational wealth transmission in the twenty-first century, one might begin by considering the changing nature of the family itself. Particularly in advanced capitalist nations such as the United States, the traditional family is showing signs of disintegration. Traditional heterosexual marriages often end in divorce, and several forms of nontraditional relationships, such as same-sex marriage, are being legitimized. Since advanced capitalist nations offer many forms of wealth that are obtainable by individuals, there is no longer a critical need for children to succeed to a parent's land. Thus, the strict family protection practiced by the inheritance systems of many capitalist nations outside the United States may seem outdated to some.

American law, unlike that of many nations, does not directly protect children from disinheritance by their parents. By contrast, other nations may choose not to aggravate certain social trends, like the atomization of family and society, which many of them are already experiencing. Their common judgment may be that, even in the twenty-first century, some homage to the family, traditional or otherwise, still needs to be paid in the field of intergenerational wealth transfer. Whether the restraints on individualism that such a judgment entails will remain the norm internationally and whether they will become the norm in the United States remain open questions.

Property Ownership

Frank Decker, Sydney, NSW, Australia

Abstract

Property ownership can be understood as the ultimate residual right that has been left with the owner after other property rights such as possession have been granted to others. Providing the legal basis for the core operations of a credit-based monetary economy, property ownership allows individuals to enter into economic dealings by issuing claims to their property, while retaining possession or control of their assets. Historically, claims to property took the form of book debts, debt instruments and money and were enforced through elaborate legal systems. Networks of creditor–debtor relationships then began to regulate production, distribution and consumption via interest-bearing loan contracts and became the characteristic form of economic organization in ancient and later modern ownership-based economies around the world.

Introduction

Property ownership refers to the right of ownership over property. In contrast to possession, which governs the physical use, occupation and control of an object, ownership can be understood as the ultimate residual right left with the owner after other property rights, such as possession have been granted to others (Goode, 2004). The occupier of a house may, for example, retain possession of the house but transfer ownership to a banker as security for a loan. This conceptual separation of ownership and possession in turn provides the underlying legal basis for the core operations of any credit-based monetary economy such as credit sales, lending, leasing, the taking of loan security and the creation of money (*see* Property Rights and Urban Planning.).

Property ownership as a characteristic element of society is believed to have originated in the Greco-Roman world (Pipes, 1999; Bethell, 1998; Heinsohn and Steiger, 2013). After the fall of the Roman Empire, property ownership reemerged on a significant scale in the fourteenth century in England and – in line with the transformation and success of the English economy – was transplanted or adopted in many parts of the world. Unlike tribal and command systems which apply customary rules or coercive mechanisms, the members of ancient and modern ownership-based societies enter into contractual creditor–debtor relationships that regulate production, distribution and consumption and in which property ownership is the dominant feature (*see* Property Rights and Urban Planning).

In the wake of the Communist Manifesto, the concept of property ownership fell into intellectual disrepute and for many decades was viewed disparagingly by Western intellectuals (Bethell, 1998). As a result of this peculiar history, property ownership has suffered from a long period of theoretical neglect. It was not until the fall of communism made it clear that more than deregulated markets and foreign investment was required to build successful economies, that the economic significance of property ownership was fully recognized and placed within coherent theoretical framework (Heinsohn and Steiger, 1996, 2013; Stadermann and Steiger, 2001; Stadermann, 2006; Steiger, 2006; Decker, 2010; see also Bethell, 1998; Pipes, 1999; De Soto, 2000).

This article deals with the economic consequences of property ownership, which are the development of a system where claims to property (including money), ownership premium and interest become the core elements underpinning economic organization. The first section shows that, following an initial distribution of former feudal land holdings to its members, ownership-based societies were dominated by the issue of debt and debt enforcement. The second section explores the question of how claims to property were made quantifiable and ultimately settled, describing the emergence of money of account and settlement assets including coinage. The third section outlines how owners deployed their assets by creating claims to their property, documented in the form of book accounts, various debt-related instruments and importantly money. The fourth section describes how property ownership gives rise to the ownership premium and interest, outlining why modern ownership-based systems suffer from periodic crises but also tend to innovate and grow.

Claims to Property and Their Enforcement

Both the Roman civitas and the Greek polis are regarded as the prototypes of ownership-based forms of social and economic organizations that emerged in the Mediterranean and in many parts of the Near East. Ownership represented a radical, discontinuous and permanent shift from the preceding feudal organization (Finley, 1981; Heinsohn, 1984). It has been argued (Heinsohn, 1984) that following a series of cataclysmic events, revolutionaries divided the former feudal land holdings and created a new and free society, a 'government without a king and a democracy' (Plutarch, Theseus XXIV, 2–3). Each citizen now stood 'on an equal footing' (Plutarch, Theseus XXIV, 2–3) and outside the collective social safety networks of tribe (reciprocity) or feudal seigneurie (emergency rations). This meant that the giving of credit and the entering into debt became a necessary means of dealing with bad harvests, variability of yields and other emergencies, which could affect one land allotment but not another. This new type of credit, now occupying a central role in the ancient economy, was no longer based on the rules of reciprocity between helping friends or neighbors (Heinsohn and Steiger, 2013). In contrast, debts now became legally enforceable and the newly established systems of law

provided the creditor with powerful claims to the general property of the debtor or to the debtor as a person.

It is telling that the earliest legislation in ancient Greece and Rome extensively deals with the issue of credit and debt. Both Athens and Rome were confronted at an early stage with debt-bondage crises that 'involved a substantial section of the citizenry' (Finley, 1981: 160). Debt bondage or 'nexum' has been interpreted by some as a premonetary form of interest, where a debtor bound himself to a creditor to provide labor services during the period of the loan (Heinsohn and Steiger, 1996). If the loan was not repaid when due, the debtor remained in debt bondage and was bound to perform the same services until the eventual repayment of the loan (Finley, 1981). Solon's reforms as ruler of Athens (*c*.594 BC) were reported to have included the freeing of debt-bondsmen, the abolishion of debt bondage in the future and the cancellation of existing debts (Aristotle, Ath. Pol. 2.2; Finley, 1981). The latter was signified by the removal of mortgage stones ('horoi'). In Rome, the law of the 12 Tables (*c*.451/50 BC) set a maximum interest rate (Tables 8 and 18). Evidence indicating the periodic cancellation of debts and the release of people who were enslaved for debt also provide the prime examples of legislation in early Mesopotamia (Westbrook, 2003).

The Greco-Roman procedures for enforcing debts and claiming property were comprehensive. For example, in the law of Athens (*c*.435–322 BC), an action could be brought by the owner to claim property from another person. On non-performance an action for ejectment ('dike exoules') could be brought to seize the property due to him or other property of equal value. Hence, a debtor's property was always subject to a potential forfeiture until a debt was repaid (MacDowell, 1978). The Roman law of the 12 Tables (3, 1–6) outlines a treatment which was particularly harsh by modern standards ('manus iniectio'). If judgment was given against the debtor and payment had not been made within the required time, creditors could kill the debtor or alternatively sell him as a slave abroad (Kaser, 1996), thereby providing the debtor with a strong incentive to transfer ownership of his property assets or his services to the creditor. In later times, the execution against the debtor's property was introduced as an additional option, with that property being subsequently sold by public auction to pay for an unpaid debt or transferred to the creditor in settlement (Kaser, 1996; Crook, 1967).

Debt enforcement also remains of central importance in modern ownership-based systems. For instance, English law allowed creditors to imprison insolvent debtors until the debt was satisfied (the writ of 'capias ad satisfaciendum'), a practice that was only abolished (with some notable exceptions) by the Debtors Act of 1869. Thereafter, the seizure of the debtor's assets and the distribution of sales proceeds to creditors in proportion ('pari passu') to the quantity of their claims superseded the imprisonment of debtors as a result of private actions.

An alternative way to safeguard the recovery of property from defaulting or insolvent debtors is the taking of loan security. This typically gives the secured creditor priority over other unsecured creditors and the power to sell the asset identified as loan security and be compensated from the proceeds. Security rights are well evidenced in ancient Greece. About 250 'horoi' (mortgage stones) have been found and documented (Millett, 1985). These were placed on the land, inscribed with the particulars of the loan and provided public notice that the land was hypothecated. It is believed that possession of the property stayed with the debtor and that the creditor acquired ownership or a right to enter the property on default (Finley, 1951; Harrison, 1968). The law of Athens also used the pledge, where a thing (usually a movable) is handed over to the creditor as security for a loan (Harrison, 1968). Roman law security rights were the 'pignus' (pledge), where possession of the loan security was transferred to the creditor; the 'fiducia' (mortgage), where ownership was transferred to the creditor; and the 'hypotheca' (hypothec or charge), where possession and ownership remained with the debtor, but the creditor acquired a charge against the asset, which could be enforced against third parties (Kaser, 1981). In turn, Roman law has become the model for modern security law (*see* Property Rights and Urban Planning; Security: Commercial Transactions.).

Claims to Property: Their Quantification and Settlement

Entering into debt and the enforcement of debts as claims against the general property of a debtor raises two important questions. First, how can debts and consequential claims to inherently different property assets be quantified and be reduced to a common economic measure? Second, how can claims to property be ultimately settled?

The question of measurement of property is reflected in the development of abstract units for debts or monies of account (Steuart, 1767). Historically, these were often related to weight units as, for example, in the Babylonian system of 'shekel' (of c. 8.4 g), 'mina' (of approximately 502 g = 60 shekel) and 'talent' (at 60 'minas'). In the Greek system, the money of account was based on the system of 'obol' (derived from 'spit') and 'drachma' ('handful' of six spits = 6 'obols'). Both terms also meant weights. 'Drachmas' were then related to the 'mina' ('mna', 100 'drachmas' = 1 'mina') and 'talent' (=60 'mina') of the Babylonian system (Chantraine, 1979a,b,c).

When weight units are the basis of a money of account, the specification and settlement of a debt can be expressed in terms of weighing out a specific quantity of a commodity. This principle is also reflected in the Roman 'mutuum' (cash loan) requiring the weighing, counting or measuring of fungibles (Roby, 1902). For instance, an obligation of 1 'shekel' is settled with 8.4 g of silver, as a consequence of which the price of 8.4 g silver is set to one (silver) 'shekel'. The money of account is (silver) 'shekel', with the price represented by the number of units ('1') and not, as is commonly assumed, the quantity of silver (Stadermann, 2006; Decker, 2012). As in the case of the silver commodity itself, all other property assets are then assigned a price in numbers of (silver) 'shekels', found for example, in Ur III (*c*.2150–2000 BC) merchant balance sheets (Postgate, 1992). Silver attained a special role only in so far as it became the preferred asset to specify and settle debts ('settlement asset', Decker, 2010, 2012). Other commodities were used for this purpose, such as, copper in ancient Rome. In this way, claims to inherently different property assets were able to be specified as nominal obligations with an absolute price expressed in the designated money of account.

Final settlement could occur by delivery of a defined quantity of a commodity. However, the common money of account opened up the possibility of other modes of discharge. Mutual obligations could now be set-off or payment could occur by delivery of an alternative good with the same price if this was accepted by the creditor. Both forms of discharge could be affected in account books and did not require a physical settlement asset or a physical exchange of goods.

The final discharge of obligations was later refined by the use of coins instead of commodities as settlement assets (Decker, 2010). The invention of coinage around the end of the seventh century BC is attributed to the Lydians (at the time under Greek influence) and was rapidly adopted by Greek city states (Seaford, 2004). Coins can be defined as shaped objects with a sign or symbol indicating or implying the number of units in the money of account. Originally believed to have been issued by individuals, coinage later came under state control (Chantraine, 1979d). Obligations and prices continued to be expressed in the same money of account (e.g., 'drachmas'), but the discharge now occurred by counting out a corresponding number of coins (Seaford, 2004; for Rome see Harris, 2008b) rather than by weighing out a certain quantity of a commodity (e.g., silver). This reflects the 'fiduciary' nature of coinage: a coin is legally accepted at its stated unit expressed in money of account, even though its intrinsic (bullion) price may deviate from it (Seaford, 2004). Obligations could now be discharged based on the principles of 'nominalism' (Knapp, 1905), which means with designated assets which 'if added together according to the nominal value indicated thereon, produce a sum equal to the amount of the debt […] regardless of both their intrinsic and their functional value' (Mann, 1971: 76).

While the reasons for the introduction of coinage are considered 'irrecoverable' (Seaford, 2004; Harris, 2008a), state-issued coinage appears to have addressed situations where shortages in supply of silver caused periodic monetary crises. These could now be mitigated by the introduction of token coinage (where the price of the material is insignificant) or debased silver coinage, both issued by the state (Heinsohn, 1984; Heinsohn and Steiger, 2013; Seaford, 2004). State-issued fiduciary or token coinages represent an obligation of the state and are issued in payment of state expenditure and received back through taxes, fines and levies. Hence they are backed by the state's power to raise taxes. There is evidence of iron and bronze coinages, coins made from silver mixed with other base metals. However, most Greek coins of the Archaic and Classical period had a relatively high silver content. While circulating locally at a premium over bullion, a high silver content would have made them acceptable outside the boundaries of the polis, where they are assumed to have traded at the price of bullion (Kraay, 1976; Seaford, 2004; Heinsohn and Steiger, 2013).

Claims to Property as Book Accounts, Debt Instruments and Money

Settlement assets such as commodities or state-issued coins allow the final discharge of an obligation. State-issued assets are attractive because the final settlement between private individuals always requires an asset 'that is not a liability of the same debtor' (Decker, 2010: 184). The advantage is the finality of such transactions; the disadvantage is that property owners have to find ways to acquire the physical settlement asset, which may be in short supply or which requires the corresponding sale of an asset. Hence, in many instances property owners avoid transactions in physical settlement assets altogether by creating and documenting claims to their property, as is evidenced in the use of book accounts, debt-related instruments and money (Decker, 2010).

Claims to property or obligations are promises to pay a sum in the designated settlement asset specified in the money of account. These are backed by the general property of the issuer and rely on the separation of ownership and lesser rights such as possession. The property owner becomes liable for the issued claim under debt recovery law, which places a temporary burden on his property, most importantly his land allotment. Hence, the claim is enabled by ownership and leaves the physical possession of the property unaffected. For example, a debtor receives a loan of barley seeds, which the creditor and debtor document in an account book or as an acknowledgment of debt with a sum specified in X units of the designated money of account. The debtor remains in possession and continues with the agricultural use of the land. The loan is then repaid at harvest time by the delivery of a quantity of barley sufficient to yield a price of X units of the specified money of account plus the agreed amount of interest. This is again documented as an account entry (or as an acknowledgment of debt) offsetting the original obligation and removing the burden on the property. No coinage changes hands in this transaction.

At a general level, the majority of economic dealings does not produce one-off transactions but create circular, self-liquidating payment flows, where one transaction is likely to be matched by another off-setting transaction. This is the reason why claims to property are particularly useful in economic dealings. Consider, for example, the situation of a merchant who supplies producers with materials, but at the same time purchases their finished products. Similarly, a producer A, who has an account with merchant B and enters into an obligation with supplier C, can pay C by ordering B to create a book entry in favor of C, assuming C also has dealings with B (Decker, 2010).

Claims to property are also the underlying basis for the creation of money. Money, here defined as a special type of claim to property, is created when a creditor (typically a bank) issues or documents claims to its property (per note or book entry) as part of a credit contract with a debtor and frequently issues and redeems these claims (Heinsohn and Steiger, 2013). Hence a producer A, after receiving book credit with his banker B as part of a secured or unsecured loan can pay his supplier C by ordering B to create a book entry in favor of C, assuming C also has a bank account with B. Money in this definition originates from private transaction needs and is distinguished from state-issued coinage or debt. The latter have been characterized as 'state-issued means of payment' and are primarily created to meet the transaction needs of the state (Stadermann, 2006).

A common and important form of credit between Roman property owners utilized account entries. Since the early Republic, Roman citizens kept account books, the 'codex

accepti et expensi', also referred to as 'tabulae' (Kaser, 1971). Obligations were documented by making entries in the account book of the creditor ('litteris obligatio' or obligation by book entry). As additional evidence, a written acknowledgment by the debtor could be set up and the transaction could be passed through the accounts of intermediaries, who in this way acted as witnesses (Kaser, 1971). The resulting obligations were referred to as 'nomina' (names of debtors). 'Nomen facere' means to make an entry and consequently to make a loan. 'Nomen' refers to the name of the debtor (Roby, 1902). 'Nomina' could be transferred and were used as a means of payment; they were the most common mechanism for large purchases and could be the subject of a pledge (Harris, 2008b; Kaser, 1981). There was a market for 'nomina' (Harris, 2008b). Courts treated law suits on book entries as it treated suits on actual cash loans and 'nomina', like movables, animals and land were seized from insolvent debtors (Roby, 1902). At a more general level, obligations could be transferred and payment delegated ('delegatio'). Evidence showing the use of written acknowledgments of debt ('chirographa') can also be found (Jolowicz and Nicholas, 1972; Mitteis, 1894). To give two examples; an inscription that preserved the Ephesian Debt Law of 85 BC refers to 'cheirographa' ('notes of hand', Wankel, 1979); and fragmentary tablets were recovered from Herculaneum which refer to chirographa in the context of account books (Arangio-Ruiz, 1948). In later periods of the Roman Empire, written debt notes became the standard form of documenting loan contracts ('cautio', Kaser, 1981). Consequently, Roman property owners could advance credit or make payments per book entry or by written acknowledgments of debt and the resulting claims could be used to discharge or set-off other obligations.

This system was further enhanced by the development of banking, which began to occupy a central role in the ancient Greek and Roman economies. For example, Athenian bankers ('trapezites' who appeared in the fifth century BC; Bogaert, 1994) made payments on behalf of their customers and documented these transactions in their book accounts (Bogaert, 1994). The volume of bank lending is believed to have been extensive and bank accounts were widely held (Cohen, 2008). Commercially active customers are known to have held accounts with the same bank, increasing the likelihood of book entry set-offs occurring. For instance, the maritime traders at Athens had accounts with the bank of Pasion, Athen's largest bank (Cohen, 2008). Banking was also widespread in Rome. Roman bankers (in evidence from 318 BC; Andreau, 1999) documented operations that effected an account in a register ('rationes'), which was required by law to be produced at court when a client was involved in a law suit (Andreau, 1999). Bank clients could order their bankers to make payment to other parties and checks existed in some areas (Andreau, 1999). Bank advances created by book entry could be secured by mortgage ('fiducia') (Roby, 1902). There is evidence that ancient banks practiced 'fractional reserve banking', i.e., bank funds created through lending by book entry clearly exceeded the physical coin reserves (Cohen, 2008; Mrozek, 1985; Harris, 2008b; Bogaert, 1994). Consequently, it has been argued (Decker, 2010) that the book credits created in ancient economies by individuals and increasingly bankers as part of their lending activities represent one of the early instances of (ownership-based) money.

While there is still some debate about the economic role and significance of book accounts, debt instruments and bank deposits in the ancient economy (Harris, 2008b), overwhelming evidence of their importance is available from early modern Europe. Like their Roman predecessors, private individuals kept book accounts and periodically set-off debts against debts (Kerridge, 1988). Accounts were complemented by claims to property known as 'negotiable instruments' (Goode, 2004) including the bill of exchange (an order to another party to pay a sum of money) and the promissory note (a promise to pay a sum of money). Negotiable instruments were designed to be transferable to other parties. The underlying basis of bills and notes is property ownership: on nonpayment a holder can sue the parties to the bill or note and in the worst case have the parties' assets seized and sold through a judicial process and then be compensated from the proceeds.

Use of, and reliance on, book debt and negotiable instruments was extensive. For early modern England it has been estimated that the ratio of coinage to notes, bills and book debt was at least 1:20 (Kerridge, 1988), with manufacturers, shopkeepers and tradesmen 'involved in complex webs of debt and credit' (Wrightson, 2002: 293). It was common practice to set off debts against each other, with only the remaining balances settled in coin or with payment being even further deferred by writing out a promissory note (Decker, 2010). Out of this practice evolved a system that relied on factors and middlemen, for precisely the reason that it greatly increased the opportunities for these mutual set-offs to occur (Rogers, 1995). Bills, notes and book accounts were also extensively relied upon in the Colonies of the British Empire (see, for example, Decker, 2010, 2011; Michener and Wright, 2006). They also provided the much needed elasticity of funds in the take-off phase of the industrial revolution in Europe (North, 1994). A review of nineteenth century civil law cases in England, New South Wales and Connecticut show that at the time about 90% of all cases were debt related (Kercher, 1996).

In modern ownership-based societies, money predominately reemerged in the form of bank notes (promissory notes payable to bearer on demand) and bank deposits. These were issued or created by private entities, often merchants or industrialists who, based on their central role in the payment system, developed into 'bankers' (Pressnell, 1956; Lipson, 1956; Decker, 2010, 2011). The typical nineteenth century private note-issuing bank such as the Bank of England, the numerous English country banks (Pressnell, 1956), colonial banks (Decker, 2011) or the banks of New York (Gibbons, 1858) created money by discounting bills of exchange and promissory notes (i.e., the purchase of bills and notes at a discount to their face value) and by making secured and unsecured loans. The debtor received the discount or loan proceeds in the form of the bank's notes or as a deposit entry in the bank's book accounts, which became the standard means of payment. Bank capital was held to ensure that notes could be redeemed on demand and to provide a buffer for unforeseen loan losses. Consequently, the soundness of the private note-issuing bank was based on its capital and the quality of its loan assets, which were underpinned by the property of its debtors (Heinsohn and Steiger, 2013). Broadly

the same principles apply to modern central banking systems, where money is created via commercial banks that enter into secured loan contracts or repurchase agreements with a central bank (Heinsohn and Steiger, 2013).

Bank money becomes of central importance for an ownership-based system in three ways. First, debtors are freed from the obligation to redeem their own notes on demand; an obligation which is now performed by specialized bankers who are compensated with interest (Heinsohn and Steiger, 2013 see already Steuart, 1767). Second, bank notes allow the ready monetization of property assets, which turns these into generally accepted purchasing power without requiring the sale of the underlying assets (see already Steuart, 1767). Third, banks can set and stabilize property prices as measured in their own notes. This follows from the fact that in each discount or loan operation, a bank must specify a price of the underlying property assets in its own notes (Heinsohn and Steiger, 2013; Decker, 2013; Stadermann, 2006). By regulating the amount of bank money created and the rate of interest, a bank safeguards the purchasing power of its notes, thereby creating a price anchor for nominal obligations, which is indispensible in any ownership-based system. For example, nineteenth century banks throughout the world set the price of gold in their currency units, by purchasing and selling gold and commercial bills (Stadermann, 2002, 2006). Absolute prices for all other property assets follow by comparison from the bank determined prices for assets underlying loan and discount operations (Heinsohn and Steiger, 2013).

Ownership Premium and Interest

Following the initial distribution of property allotments, members of ownership-based societies use claims to their property to enter into economic dealings that regulate production, distribution and consumption. While property is subject to such claims – as for instance when assets are used as security for a loan or to back 'nomina', promissory notes, bills of exchange or bank notes – the potential claims of third parties place a burden on the property. The owner, while still in physical possession or control, is no longer able to freely dispose of the asset. A very important consequence of property ownership is therefore that any property asset that is unburdened and free, must carry a premium: the ownership premium (Heinsohn and Steiger, 2013). In turn, the loss of ownership premium must be compensated. The compensation takes the form of interest, which is a characteristic element of both ancient and modern ownership-based systems but is absent in tribal and command systems (Heinsohn and Steiger, 2013).

When a note-issuing bank creates notes for a debtor as part of granting a loan, the bank has to underwrite the issued notes with its capital. Capital is required as the bank remains liable for the full nominal amount of the issued notes and, in order to protect its solvency, must be able to absorb even unidentified and improbable loan losses. For the same reason, the debtor must provide loan security to the bank or provide an unsecured claim to his property (enforced by court order if needed) in return for the loan. Both parties lose ownership premium in this process, as the bank has to set aside (burden) its own capital to back the note issue, while the debtor has burdened his assets by way of loan contract. The bank's loss of ownership premium is compensated by interest from the debtor. The loss of ownership premium experienced by the debtor is compensated by the liquidity premium attached to the money notes, because they can discharge obligations at any time. Interest therefore compensates the loss of ownership premium and not, as is commonly assumed, forgone consumption or a loss of liquidity, which neither creditor nor debtor experience in this transaction (Heinsohn and Steiger, 2013).

The existence of interest implies that the amount of money repaid must exceed the money advanced as capital. Therefore, for the economy in aggregate 'it is always the case that less money is lent than owed' (Heinsohn and Steiger, 2013: 113). The need to create money via interest-bearing loan contracts is therefore extorting an ongoing pressure to create a surplus, by way of production or otherwise, that can be converted into additional money to service the interest on outstanding loans. Assume, for instance, that a set of loan contracts is rolled over for a second period, as producers seek to maintain their level of economic activity. In this case, the volume of money at the beginning of the second period, as is reflected in the sum of outstanding money-creating loan contracts, must be the sum of the original loan principals plus interest. Because the money required for the interest payments must also be created in loan contracts (here assumed to run over the same period), the money supply increases in each period by the aggregated amount of interest.

It has long been argued that an interest-induced increase in the money supply was a material issue for the Roman economy and led to periodic liquidity crises (Frederiksen, 1966; Mrozek, 1985). Because the supply of money in the form of 'nomina' and bank deposits was constantly growing (at a typical interest rate of 12% p.a. the money stock would double in about 6 years) an ever increasing gap occurred between the volume of money and the volume of state-issued settlement assets in the form of coins (Mrozek, 1985, 2001). As coinage was needed for the periodic settlement of balances, their increasing scarcity combined with uncertainty created by war, political crises or otherwise, periodically led to a collapse of credit markets and falling land prices. For instance, debt and liquidity crises impacted Rome in 193–192 BC, the 80s BC, in 63 BC, in 49 BC and in AD 33. Responses by Roman authorities included the cancellation of debts, staggering dates for repayment, interest-free loans, settlement in property rather than coin, measures to limit the hoarding of coins and measures to compel Romans to invest in Italic tribal land (Andreau, 1999; Mrozek, 2001; Frederiksen, 1966).

Liquidity crises continued to be a feature of modern ownership-based systems. In the nineteenth and twentieth century, the adverse impact of the elasticity limitations inherent in state-issued payment instruments led to the creation of central banks as lenders of last resort. This made money issued by central banks in loans secured by eligible property assets the leading settlement asset (Decker, 2010). The underlying principle of last resort lending is that everyone with sound loan security should have access to liquidity in a crisis. This principle emerged in response to the English crises of 1793, 1811 and 1825/26, where the Bank of England had to relax its standards for eligible bills and advanced its

notes on exchequer bills (secured by merchandise) and later directly on merchandise to stay the panic (Bagehot, 1873). The implication of last resort lending is that all principal property classes of an economy need to be convertible into central bank money in a crisis, once again emphasizing the property-based nature of money.

The interest-induced pressure to return a larger nominal amount of money than borrowed is also interlinked with the factors that drive economic development, growth, productivity and technical progress. In the case of a producer, the realized price of the production output, i.e., quantity times unit price, must be larger than the money advance and result in a profit (Heinsohn and Steiger, 2013). Because obligations are nominal, a surplus (for the economy as a whole) can be realized by a higher volume of production outputs or higher prices. The resulting inherent upward pressure on prices must be counteracted by a restrictive monetary policy (Stadermann, 2002). Consequently, producers must compete for bank money, while being exposed to fixed repayment obligations and uncertain sale proceeds. They will seek to outperform their competition by lower prices or the introduction of new and innovative products (Heinsohn and Steiger, 2013).

A special characteristic of the modern ownership-based system is the dominance of free wage labor. In contrast to the chattel slave, who was part of the production assets and could be mortgaged and sold, a wage labourer obtains a money wage. For the producer, the money advance required to pay wages must be raised beforehand and cannot, unlike equipment or slaves, be financed by using the wage laborers as collateral (Decker, 2013). Money expended on wages is also lost if the production outputs cannot be sold at the required price. Consequently, it has been argued that producers are constantly trying to reduce the level of wage labor, thereby creating a state of constant technical innovation, which has become a unique characteristic of modern ownership-based systems (Heinsohn and Steiger, 2013). This inherent tendency to generate productive growth has been reflected in unparalleled economic growth and prosperity in developed countries around the world. In contrast, the lack of access to formal ownership and security rights for the majority of people in developing countries has been identified as the key reason for their relative lack of development (De Soto, 2000). It follows from this that property ownership and the associated monetary system of production is the main factor for triggering economic development and not as is often assumed the inefficiencies arising from common as opposed to private control over resources.

While the ownership premium creates the demand for interest, it also reflects the readiness to burden property by entering into new loan contracts and therefore the willingness to invest. The ownership premium will rise sharply during a credit crisis or in an economic downturn as, for example, following a period of 'over-investment' due to an industry-wide innovation cycle, such as revolutions in transport, energy and information technology (Heinsohn and Steiger, 2013). When the ownership premium exceeds the expected returns on capital, owners will reduce the amount of property that is made available for the purposes of money creation. As owners try to protect themselves from asset losses, good loan security becomes rare in a crisis and central bank action is hampered because it cannot create the missing property required for debtors to obtain fresh loans (Heinsohn and Decker, 2010). In a deep downturn a redistribution of property ownership – at times facilitated through temporary state ownership, bail-outs and subsidies – may become the only way out of the crisis.

Property Rights and Urban Planning

Barrie Needham, Radboud University, Nijmegen, The Netherlands

© 2015 Elsevier Ltd. All rights reserved.

Abstract

A property right gives someone the right to use a 'thing' – this case, land and buildings – in a particular way. The right is a legal relationship between the recognized user and all others who have to respect that use. Property rights are created in order to regulate the traffic between legal persons, and in that function they affect the way in which cities are formed and used. Urban planning necessarily restricts the way in which people may use their property rights, and for that reason is subject to political and economic analysis.

The Relevance of Property Rights for Urban Studies and Planning

People and organizations can own property rights in land and buildings. How they exercise those rights can affect the form of the city and the way in which it is used. It follows that the nature of the property rights and the legal context in which they are exercised is important for the life of the city. In addition, when public authorities practice urban planning, they usually have to restrict the exercise by the property owners of their rights. That makes urban planning a political activity, for people value the freedom which property rights can offer.

For those reasons, a good understanding of the nature of property rights is essential for urban studies and planning. Here, attention is paid to how property rights are created and can be changed, how they are embedded in a country's legal system, why they are important not just to individuals but also to the wider society (cities could not function without property rights), and the many ways in which they are restricted (and not just by urban planning). Moreover, it is shown that urban planning can be more effective and sensitive if it is based on a thorough understanding of property rights.

The Nature of Property Rights

There are many things which can be used in a variety of nonexclusive ways by different people. A house, for example, can be used for living in by someone who rents it from someone who uses it as a source of income and who, in turn, pays another person for the use of the ground on which the house stands. It is possible that the occupier sublets a room in the house to yet another person, or a shed in the garden to someone for use as a garage. Also possible is temporary use of the house, for example, just for the summer season. If one or a collection of those uses is protected by law – the person who exercises the use can by force of law prevent others from interfering with that exercise – that use is called a property right. The example shows that there can be more than one property right in one 'thing.' There are various types of 'thing' over which property rights can be exercised: immovable property (land and buildings), movable property (chattels), intellectual property (e.g., authorship of a book), and water (e.g., extracting water from a river). For this article, we restrict ourselves to rights in immovable property, alternatively called landed property, real estate, or real property.

It follows from the above definition that a property right is not a relationship between a person (the holder of the right) and a thing, but between persons: between the holder of the right and all others who are required to respect that right. This was stressed by Hohfeld (1913, 1917) when he pointed out that whenever there is a person enjoying a right, there is another person with an associated duty, namely to permit the first person to enjoy the right.

If this power is to be exercised effectively, it must be possible for the holder of the right to use force against someone who transgresses it. If, for example, a tenant has a formal right to occupy a room in a house and the landlord wishes to eject him for reasons outside the contract, the tenant must be able to seek protection against the landlord. In a state with a rule of law, the only entity entitled to use force is the state. So the plaintiff (the one whose right is transgressed) cannot himself force another to respect his right: instead, he is able to ask the court to take action against the defendant (the transgressor). This is crucial: an interest in a thing is a right only when it is protected by law. If the right is transgressed, it is for the holder of the right to take the initiative get it upheld. This is the essence of civil, or private, law. A plaintiff asks the court to take action against a defendant. A property right consists, therefore, not only of a description of the use which may be exercised, but also how it may be defended in law. The latter requires also that the nature of the use and the person of the user must be registered (for example, through a notary or in a cadastral register).

It follows from this that property rights are a social creation: there can be no property rights without agreement on what they entail (the task of the legislature) and without the possibility of enforcing them legally (the task of the courts). It is not that something is protected because it is a property right, but that something becomes a property right by being protected (Bromley, 1998: 25). Or "It is not property which is owned, but ownership which creates property" (Denman, 1978: 26).

In this respect, a right can be distinguished from a lesser interest in land. I have an interest in firm foundations under my house, and in many countries the state considers that interest to be so important that it gives me the 'right of support': if my neighbor digs a hole in her garden so big that it endangers the stability of my house, I can ask the court to stop her. I might have an interest also in the color in which my neighbor paints

 http://dx.doi.org/10.1016/B978-0-08-097086-8.74032-3

her house: I find, for example, vivid pink disturbing. But the state might not consider that interest to be big enough to give me the legal right to proceed against my neighbor: that property right does not exist.

The Social Function of Property Rights

Property rights are created in order to regulate the 'traffic' between legal persons. Before someone builds a house on a plot of land, he wants to know precisely what his rights are to that land: for example, has another person a right of way over it, the right to repossess it after 50 years, or the right to discharge water over it in case of excess water upstream? Before a bank takes a mortgage on a house in return for a loan, it wants to know whether the mortgagee has given tenancy rights to another person. Clear and enforceable property rights reduce uncertainty, foster trade and good relationships, create a stable framework for long-term investments, and give continuity to a society. It is for this reason that throughout the ages states have created – or recognized existing de facto – property rights.

Although all states have created property rights, those rights are not the same in all states. In particular, most states recognize and protect the right of citizens and other private legal persons to own 'things,' but there are big differences between states in what the citizen is entitled to own. Socialist and communist states, for example, often restrict (or have restricted) the right of citizens to own land, or a house, or more than one house, or the means of production beyond tools and equipment for own use. In the Soviet Union, the right of ownership was defined in almost the same way as in market states: the big difference was in what could be owned (Honoré, 1961).

The Creation of Property Rights

There are no property rights without recognition and enforcement by law: property rights are created. It has been suggested that this creation follows certain regularities. Ellickson (1993) put forward the 'efficiency thesis' that 'land rules within a close-knit group evolve as to minimize its members' costs.' Demsetz (1967) put forward the thesis that when conditions change, resulting in valuable external effects which cannot be traded, property rights are changed so that those external effects can be internalized and thus realized. However, more recent work has cast doubt on such evolutionary laws. North (1990), for example, argues that property rights are made and changed by those with power, and that those people often want to preserve their privileges. He argues also that path dependency strongly influences the way in which legal rules change. Barzel (1989) argues, nevertheless, that economic analysis can help to explain why property rights change.

A country has often developed its formal legal system in close connection with its system of property rights: the wish to define and enforce property rights has influenced the legal system. Alternatively, a society may reform its legal system deliberately in order to change the existing system of property rights (as happened after the French Revolution and in the United States after the declaration of independence). Path dependency will influence the creation of those legal rights, and informal practices will influence the formal laws and how they are applied. It is for such reasons that it is common to talk of a country having a land system, which is an amalgam of formal rules and informal practices. In a mature country, this makes a consistent and coherent whole with the other aspects of the legal and political system. It follows that the land system and the property rights contained within it cannot be changed easily, apart from small modifications.

Those small modifications are part of the continuous adaptions to the law. For example, laws to regulate the relationship between landlord and tenant are often changed. Or it is ruled that a 'presumptive right,' such as the right to a view or the right to make a loud noise, should be taken away. Radical changes in property rights in land, such as land reforms, are rare because they would disrupt deep social and economic relationships. (It should be noted that the above applies to changes in the private law regulating property rights. The way in which property rights may be exercised can be changed by changes in the public law, such as for land-use planning or environmental policy. This is discussed later: restrictions on the exercise of property rights.)

When property rights are changed, the nature of the legal system affects the way in which that happens. Under English Common Law, for example, private parties might agree voluntarily on a new type of use. If one of the parties breaks that agreement, the other party might take the case to court. If the court judges in favor of the plaintiff, then a new property right has been created. (It is in this way that in some countries 'squatters' rights' have been created.) If, on the other hand, the law is codified, a new property right can be created only by changing statute law: it might be that the occasion for doing that is changing social practices, but those practices become legally recognized only after a legislative change. (For example, it was not possible in the Netherlands to acquire the transferable right to own an apartment: there was strong social pressure to introduce that; it was created by law in 1951.)

Varieties of Property Rights

There is an enormous variety of property rights in existence: apparently societies have found it useful to create such differentiation.

In some countries, there is the right to full ownership, which includes all possible uses of that thing. This is the Roman law concept of dominium, the right to use something, enjoy it, and dispose of it 'de la manière la plus absolue' (in the terms of the Code Civil Napoleon, 1804, article 54.4). This finds its expression in Dutch law also, where ownership is defined as 'the most comprehensive right that a person can have over a thing' (Civil Code, article 5.1). (It should be noted that the idea of making an exhaustive list of all possible uses is explicitly rejected, for additional possible uses might arise, which would nevertheless fall within the right of full ownership.) In addition, there are partial rights, which give the right to use the thing in just one or a limited number of ways. The owner of the full right can split

off partial rights and dispose of them. He who exercises a partial right is then not the owner, but the holder, of that right: he exercises it with the permission of the owner.

In countries with an Anglo-Saxon legal system, the starting point is not the full right of ownership, but partial rights: there are many separate property rights in the thing, each of which can be owned by a different person. There is full ownership if certain of these rights (a particular 'bundle of rights') are combined in such a way that they can be exercised by one person. This is fee simple, in Anglo-Saxon terms, and the rights included need not be comprehensive: certain partial rights can be owned and exercised by others.

The particular set of rights which constitute 'full ownership' varies from country to country (e.g., Kruse, 1939; Honoré, 1961). Nevertheless, it has been suggested that full ownership of a thing always includes:

- the right to exclude others from that thing (*usus*);
- the right to dispose of (to alienate) that thing (*abusus*);
- the right to the 'fruits' derived from that thing (*usus fructus*).

(The Latin words in brackets are from Roman law on property rights.)

Legal ownership of a 'thing' can be more limited than full ownership. It must include the right to dispose of it (perhaps only after a partial right has expired: it is a reversionary right) and it must be for an indefinite period.

Partial rights can give use of landed property in very many different ways (and see Stake, 2000):

- The right to a particular use of the land, where that use can coexist with other uses of the same land. This is an 'easement.' A fishing right is an example of this, as is a right of way.
- The right to use, temporarily, the whole parcel of land or part of it, to the exclusion of all others. If the right is to a part, that part can be separated from the rest horizontally (e.g., a field on a farm) or vertically (e.g., mining rights, or air rights). Leasehold falls under this type of right. If the duration is limited, it is specified to whom the right (the future interest) will revert at the end of the term. The duration can be 'in perpetuity,' in which case there is no future interest.
- The right to the 'fruits' of the land. The fruits might be income, or 'in natura' such as crops, or occupation.
- The right to 'alienate' the land or a right on it.
- The right to attach conditions on how the new owner/holder of the land may use it. A covenant is an example. Restrictive covenants (specifying what the new owner may not do) are more common than positive covenants (specifying what the new owner must do). Home owners' associations use positive covenants: someone buying a house is required to become a member of the home owners' association and to delegate to that association certain powers for managing the housing estate.
- The right to use, but only for a specified period. Easements are often in perpetuity, leaseholds usually for a limited period, as is 'usus fructus.'
- The right to split off one or more of the possible uses and to transfer this to someone else. An example is the right of a tenant to sublet part of the premises.
- The right is to be shared and jointly exercised with others (co-ownership). For example, it can be arranged that spaces which are used by all those living on a housing estate (a car park or green areas) be owned jointly by all the residents.
- The right to exercise the use without interference from owners/holders of rights on other pieces of land. (This might be realized differently, under generic law concerning nuisance or good neighborliness.)
- The right is settled on the land or on the person holding/owning the land. An important distinction, derived from Roman law is between material rights, or 'rights in rem,' and contractual rights, or 'rights in persona.' The former are attached to the thing irrespective of the (legal) person exercising the rights: they 'run with the land.' Therefore, they can be freely traded. The latter are not attached to the thing but may be exercised only by the (legal) person specifically named in connection with that right: they cannot, therefore, be traded. For example, in some countries a tenancy lease can be traded, but a rental agreement cannot. A contractual right usually ends when the named person leaves voluntarily, or dies, or at the end of the contractual period.

Often, another type of distinction is made, namely between:

- the rights of private ownership;
- the rights of shared ownership; and
- the rights of public ownership.

This, however, is not useful. All property rights are 'private' in the sense that the holder can go to court to protect his right. A municipal authority, for example, has a 'private' right to occupy the offices it uses, and in principle all legal persons can hold any property right, unless the law of the country forbids it. For these reasons, it is better to talk of different ways of holding, or managing, property rights. Bromley (2004) calls these 'property regimes.' He uses Hohfeld's concepts (see earlier text) and distinguishes between:

State property: Individuals have the duty to observe the use and access rules determined by the controlling or managing state agency. The agency has the right to determine the use and access rules.

Private property: Individual owners have the right to undertake socially acceptable uses, and have the duty to refrain from socially unacceptable uses. Others (nonowners) have the duty to refrain from preventing socially acceptable uses and the right to expect that only socially acceptable uses will occur.

Common property: The management group (the owners) has the right to exclude nonmembers, and nonmembers have the duty to abide by the exclusion. Individual members of the management group (the co-owners) have both rights and duties with respect to use rates and maintenance of the thing owned.

Nonproperty: No defined group of users or owners, and the benefit stream is open to anyone. Individuals have privileges and no rights with respect to use rates and maintenance of the thing. That latter is an open-access resource.

The great advantage of such a classification is that helps to avoid much careless thinking about the 'tragedy of the commons' (Hardin, 1968). Nonproperty – open-access

resources – can indeed by overexploited. But there is no reason why common property should be, if it is well managed by its members. Ostrom (1990) has done particularly useful work in analyzing the property rights necessary for managing 'common pool resources' (as she calls them) to great social advantage.

Restrictions on the Exercise of Property Rights

The exercise of property rights is always limited. The person with full ownership of land might wish that 'it is my land and I can do with it what I like,' but in practice the legislature always restricts that exercise. Again we take the example of Dutch law (Civil Code, article 5.1) where the definition of full ownership quoted above is supplemented by:

- "the owner is entitled freely to use the thing and to exclude others from that thing, as long as this use does not infringe the rights of others, nor the constraints imposed by written and unwritten law" and
- "the owner of the thing is owner also of the benefits arising from that thing, apart from any rights that others may have."

The restrictions arise partly from the contents of the right itself. Apart from the right of full ownership (which might include all possible uses, known and unknown – see earlier text), all other property rights are partial and therefore restricted. Sometimes these restrictions are entered into voluntarily. For example, if the owner of a freehold interest in land sells a ground lease on it, he has limited himself contractually: he may not use his land in other ways during the period of the ground lease, and the lessee may use the land only in accordance with the terms of the lease. Such restrictions can be enforced under civil, or private, law. Other restrictions which can be enforced under civil law are not entered into voluntarily, such as nuisance or 'good neighbor' laws, including certain laws about water extraction or discharge.

Another type of restriction is imposed by the state. For example, the owner/holder of a right on land (even the right of full ownership) might not be allowed to discharge poisonous fumes or polluted water. Under planning legislation, the restriction is often imposed that the land owner may change the use of that land only in certain ways: for example, the owner of a dwelling house may change its use to a small professional office, but not to a café. Under building legislation, there is usually the restriction that nothing may be built without first acquiring a building permit.

The most drastic restriction on property rights imposed by the state is expropriation: the state may acquire the full ownership, or a partial right (e.g., nationalization of development rights in England and Wales in 1947) against the wishes of the owner. It is in this connection that the famous statement in the French Declaration of Human Rights must be understood: that property is 'inviolable et sacré.' This was intended to protect property owners against arbitrary expropriation and against expropriation without proper compensation.

The restrictions imposed by the state are regulated differently from those included in the terms of the property right. In the latter case, a transgression of the right (a breaching of the restriction) is enforced only if a legal person asks the court to take action: otherwise, the state does not intervene. Where the restrictions are imposed by the state, it is the state itself which takes the initiative if the restrictions are breached. Such restrictions are imposed and enforced under public, or administrative, law.

When the state imposes a restriction on the exercise of a property right, this takes away some of the rights of the owner/holder. Then the politically important question arises: Should the owner be compensated for that 'taking'? (Note that the question of compensation for taking does not arise when restrictions are entered into voluntarily under private law, not even when restrictions are imposed under private law, such as nuisance or good neighbor laws.) The considerations are the following. If I own a firearm, my use of it is restricted: I am not allowed to shoot people with it. Similarly, if I own a car, my use is restricted, for I may not drive at more than 50 km h^{-1} in a built-up area. In both cases, some of my rights have been 'taken away' by the state. But no one would suggest that I should be compensated for that loss. However, if the state takes all my rights (expropriation) then compensation should be paid (unless there is a legally justified 'confiscation'). But what if the state takes away just some of my rights?

In the United States this is discussed with the concept of 'police powers': these powers can be used in the interests of 'public health, safety and morals' without any compensation to those who are restricted. In that country, it has been decided that, when the owners of landed property are restricted in the exercise of their powers for land-use or environmental reasons, this is in the interest of 'public health, safety and morals.' As a result, those restrictions are not a 'taking.' The exception is when such restrictions go 'too far,' such as removing all economically viable use. That latter is a taking under the terms of the US Constitution, fifth amendment, which stipulates "nor shall private property be taken for public use, without just compensation." Under English law, compensation for owners of landed property can be demanded when restrictions mean that there is no more 'reasonable beneficial use.' In the Netherlands, a similar rule applies. There in addition, under the principle that public regulations which bear harder on some than on others should be compensated – égalité devant les charges publiques – owners can demand compensation when a plan is changed and this causes downzoning.

The Politics of Property Rights

Because property rights are a social creation (see earlier text), they can be evaluated socially, with a view to changing them in some desired way. Because this requires the legislature to change the law, this is a task for politicians.

This is not a new insight: property rights have always attracted political attention. One of the first and best-known justifications for private ownership of property was made by John Locke (1632–1704): one had a right, he said, to ownership of that which one had appropriated by one's own labors. As a corollary, he said that the task of government was to protect private property. This idea had a great

influence on those who drafted the US Constitution. "The moment the idea is admitted into society that property is not as sacred as the laws of God, and that there is not a force of law and public justice to protect it, anarchy and tyranny commence," said John Adams in 1790 (quoted in Jacobs, 2012: 74–75). The total rejection of this attitude – the anarchic 'property is theft,' so should be owned collectively, put forward famously by Proudhon (1809–65) – is not held widely, for it contradicts the centuries-old experience that property rights are useful for regulating social and economic relationships.

Although justifications for property ownership have changed greatly since those classical statements (see for example Becker, 1977; Munzer, 1990), the social value of private ownership of property is still regarded as important. It is now incorporated in the Protocol of the European Convention of Human Rights (article 1): "Every legal person is entitled to the peaceful enjoyment of his possessions. No one shall be deprived of his possessions except in the public interest and subject to the conditions provided for by law and by the general principles of international law." But this is far from giving an absolute right. That article continues: "The preceding provisions shall not, however, in any way impair the right of a State to enforce such laws as it deems necessary to control the use of property in accordance with the general interest or to secure the payment of taxes or other contributions or penalties."

In the current debate on the politics of property rights, the extreme positions can be described as: the right to full ownership should be exercised only by private legal persons and that right should be restricted only by civil/private law, and; property rights should be owned and exercised as much as possible by public authorities.

Those who argue that property rights should be owned and exercised as much as possible by private legal persons and with as little interference as possible by public authorities (that is, without restrictions imposed under public law) are moved by a distrust in government and by a belief that if property rights can be freely exchanged this will be good for economic welfare. Also, these proponents hold high the liberal value of individual freedom: people should be able to use and transfer property rights voluntarily (under minimal conditions of the law of property, tort, and contract – Hayek, 1989). They see private ownership of property as a protection against misuse of state powers. This latter argument is put forward not only by those with much property to defend but sometimes also by those with little: if 'the little man' owns defensible property rights, this can protect him against abuses of power by the rich and the powerful. This latter consideration was strong in the revolt against the 'ancien regime' in France at the end of the eighteenth century, and in the decision by many landless peasants in Europe to migrate to the United States in order to acquire land there.

Those who argue that property rights should be owned and exercised as much as possible by public authorities do so partly as a reaction against the abuse by some big private landowners of their powers (as in England, Scotland, and Ireland in the nineteenth century, also concerning the haciendas in Spain and parts of South America). There is still much misery caused by the exclusionary effects of property rights on land with, in the extreme, people without such rights being unable to get food, shelter, sometimes simple living space (Davy, 2012). In addition, there is an argument from welfare economics, namely that a free market will not produce the highest welfare if there are imperfections, such as external effects, natural monopolies, public goods: that there are very many such imperfections inherent in land and buildings; and that a public authority is able to remove or correct for those 'market failures.' The classical exposition of this argument was made by Pigou (1932). A public body can intervene in the market for property rights by, for example, restricting the types of uses to which the owner may put his land (in order to reduce negative external effects), by expropriating the ownership right (where there is a natural monopoly given by location), and by public ownership to provide public goods such as parks and open space.

This argument for public intervention derived from welfare economics has been weakened considerably by experience with large-scale public ownership of land and buildings, in particular in communist and socialist states. This has not always realized the benefits hoped for: instead there has been inertia, lack of incentives, corruption, gross mistakes, and the citizens who should have been most helped – the poorest and weakest – have not always been favored. Proponents of free markets sometimes talk of this in terms of 'public failures' when public authorities try to correct for market failures (see Wolf, 1979).

The argument that a public authority should correct for market failures has been weakened also by theoretical work. It is clear that the market in property rights for land and buildings does not always produce what people want: for example, who is to build roads which connect the parcels of land in private use, if the government cannot get hold of the necessary land? But perhaps such failures can be tackled without direct public intervention. In 1960, Coase argued that market failures arise mainly because of transaction costs and because property rights are not clearly delineated. Incomplete separation of rights creates common property, i.e., in the public domain (Barzel, 1989) and, if these rights are valued, resources are spent on capturing them. This can lead to rent-seeking and 'common property dissipation.' According to this argument, the problem of market failures can be tackled by not only Pigovian measures but alternatively by public measures to enable markets in property rights to function well, to reduce transaction costs, and to delineate exclusive property rights (Webster and Lai, 2003).

Pursuing this line of argument further, it is not useful to think in terms of the contrast between a free market in property rights on the one hand, and a strong public regulation and exercise of those rights on the other. Instead, we recognize the social arguments for strong property rights exercised by private legal persons (the classical liberal standpoint), also that exercise cannot be unconstrained or exclusive, and we look for government measures which enable the market in property rights to work better. This – which has been called proprietary governance (Pennington, 2002), or the property rights model – can be done by structuring markets in property rights in such a way that private actors working through those markets involuntarily produce socially desirable results. This approach has received considerable attention, especially as an

alternative to zoning land use (e.g., Ellickson, 1993; Needham, 2006). If structuring markets in that way cannot produce the required results (because, for example, transaction costs are high and cannot be reduced sufficiently, as is the case with roads in urban areas), then direct public actions can be justified.

The Economics of Property Rights

When a property right can be traded (and this does not apply to rights which are inalienable, nor to 'rights in persona' – see earlier text), it will have a market value. Economic theory can, thus, be applied to explain the prices of, and transactions in, property rights. The application to rights in real estate is common: real estate economics (see e.g., Harvey, 1987; Jaffe and Sirmans, 1989).

A more radical combination of economic theory and property rights is when existing economic theory is modified by incorporating into it property rights (as institutions). The work of Barzel (1989) is a good example of this. His starting point is that most exchanges of goods and services can be interpreted as the exchange of property rights over an asset. However, property rights are rarely full delineated, and obtaining the missing information costs time and money: the transaction costs can be high. Barzel introduces institutions into Walrasian (classical, micro-) economic theory. This he calls "the property rights transaction costs model" which can give a "better understanding of the allocation of resources and of the interaction of this allocation with the legal system" (op. cit. p. 117). In this way, the economics of property rights has become one strand in New Institutional Economics (see, e.g., Cooter and Ulen, 2004).

Abstract

Property is the class of things that is capable of being owned. Of greatest significance historically were land, cattle, and humans. The most important property rights are ownership, possession, and security. While possession is encountered in various forms throughout history, ownership only emerged in the Greco-Roman world and is absent from tribal communities and feudal/socialist command systems. After the fall of the Roman Empire, an ownership-based system on a significant scale began first to reemerge in England in the fourteenth century and was adopted through colonization, conquest or reform across large parts of the world.

Introduction

Commercial transactions in any modern developed economy with a legal system grounded in common law or civil law are concerned with dealings involving property and property rights. The sale of goods, the lease of equipment or land, the issue and transfer of negotiable instruments, the grant of security in support of loans, the creation of central bank money, and the enforcement of debts are all based on property rights, which create the underlying basis of economic activity and business operations.

The term 'property' is ambiguous but it may be explained as the class of those things ('res' in Roman law) that can be subject to property rights and consequently are capable of being owned. In turn, the term 'property rights' can be used to identify the relationship between an individual and a thing and – most importantly – the effect of that relationship on the rest of the world including the state (Bridge, 2002).

There are a large number of different property rights that can exist with respect to a thing and the details of how such rights are implemented vary across legal systems. The most important examples of property rights are possession, ownership, and security (e.g., hypothecation) (Goode, 2004). Property rights are distinguished from contractual rights in that they can be enforced not just against a particular individual but against the world at large and furthermore they survive the insolvency of the counterparty (Goode, 2004). Different property rights can coexist in respect of the same thing and may be held by different people: the ownership of a house can remain with A while hypothecated to bank B as a consequence of B having lent funds to A to purchase the house. At the same time, possession (occupation and control) of A's house may be with C, who has rented the house from A and lives in it during the period of the loan.

This article is structured as follows. The first part explains the four building blocks of a developed property rights system – property, possession, ownership, and security. The concepts require some detailed discussion, as a persistent confusion over their legal significance exists in the literature. The terms 'property,' 'ownership,' and 'possession' are often used interchangeably and undue weight is given to the rights of use and control, which are associated with possession. Security – of critical economic importance – is rarely discussed. Hence, this part places a particular emphasis on clarifying the legal terminology, drawing out the distinction between ownership and possession and explaining security rights. The second part of the article provides a discussion of the origins and historical development of property rights, covering tribal communities, feudal/socialist command systems and ownership-based systems, including Greco-Roman and modern systems. It reveals that ownership-based systems have only existed for a relatively short period of time and that ownership – contrary to common belief – is not a universal characteristic of human organization.

Property (Things)

The term 'property' is derived from the Latin word 'proprietas,' the Roman law term for 'dominium' or ownership (Kaser, 1981; Pollock and Maitland, 1898). Under English property law, the term 'property' can however signify both the right of ownership (Roman law 'dominium') and the class of things capable of being owned (Roman law 'res'). This twofold meaning in terminology introduces considerable complexity, making it very important to distinguish between each of the meanings.

Property, in the sense of things that can be owned, typically includes a wide range of objects, of which historically the most important were land, slaves, and cattle. The term also includes other movable tangible objects such as ships, goods, plant and equipment, legal tender bank notes, and coinage as well as intangible property such as debts and shares in a company. However, not all things can be subject to property rights. In modern economies humans are, for example, no longer considered property and hence are incapable of being owned, sold, or used to secure loans. Other examples are the air and the stars. It is not always easy to determine what individual legal jurisdictions regard as property, particularly when the property is intangible in nature.

Important classes of property in classical Athens (around 400 BC) were land, houses, coinage, and slaves. Also capable of being owned were cattle, ships, vehicles, clothes, jewelry, and the like (MacDowell, 1978). In Roman law, an important category of property (classified as 'res mancipi') consisted of Italic land, slaves, beasts of draught, and burden (oxen, horses, asses, mules), as well as rights of way and water (rustic praedial servitudes). These had to be formally conveyed (in the

 http://dx.doi.org/10.1016/B978-0-08-097086-8.62150-5

presence of witnesses) when there was a change in owner; mere delivery of the thing was ineffective. In addition, most tangible objects such as grain, oil, bricks, food, fuel, coinage, clothes, animals, and agricultural produce were property (Nicholas, 1975; Kaser, 1981).

English law (Bridge, 2002; Goode, 2004) classifies property into real and personal property. Real property is land while personal property comprises all things capable of being owned once land is excluded. Tangible, movable things like goods, wares, and merchandise are commonly referred to as chattel property or chattels (derived from the word cattle, Pollock and Maitland, 1898). Historically, slaves were deemed chattel property in the British Colonies; slaves in the West Indian plantations could, for example, be sold and mortgaged in the nineteenth century. Another important class of personal property is intangible property. Examples are debts, shares in a company, promissory notes, bills of exchange, and intellectual property. Intangible property cannot be physically possessed. Nonetheless, documentary intangibles (that is, debts embedded in a document) such as promissory notes and bills of exchange have some of the characteristics of a chattel because they can for practical purposes be equated with tangible goods and can be subject to security rights that require transfer of possession. An important example is negotiable instruments, which can be pledged (see below).

Possession

The term 'possession' is derived from the Latin word 'possessio,' a Roman law term, which in early Roman times is believed to have signified land on which someone is 'sitting' (Kaser, 1981). Legally, possession is a right very distinct from ownership, whereas in common language possession is frequently used when ownership is the more appropriate term. As the eminent English jurists Pollock and Maitland (1898, Vol. 2. Chapter IV: Ownership and Possession) pointed out: "When a man says 'I possess a watch,' he generally means 'I own a watch.'" Similarly, property in the sense of things capable of being owned is often misleadingly referred to as 'possessions.' Conversely, the terms 'ownership' and 'property' are frequently used when the underlying subject matter is occupation, use and control, and reference should rather be made to possession. This confusion between ownership and possession is widespread in the social science literature, in particular economics (Steiger, 2006).

Although possession is incapable of a precise legal definition, it can be understood as the factual occupation, physical control, use, and enjoyment of property with the intent to exercise this control against others (Goode, 2004). Examples include not only the owner and occupier of land and the tenant of a building but also the thief in control of a stolen handbag. While this concept of possession may appear straightforward, the underlying details are of surprising complexity. The two main issues are, on the one hand, the extent of actual occupation or physical control required to obtain or maintain possession and, on the other, the identification of the circumstances in which the person who actually physically holds the thing is not considered legally as the possessor.

What amount of occupation or physical control constitutes possession depends on the circumstances of the actual case, the degree of control the nature of the thing permits, and the degree of control a possessor would customarily be expected to exercise over the thing. Legally, possession can still be maintained even though the thing is no longer within the actual immediate physical control of the possessor. Under English law, a person is considered to have possession of those movables, which not only are within his sight or reach, but also beyond his immediate control such as the books in the room next door and implements left in a field. A person remains in possession of the tables and chairs inside the house he occupies whether he is in the house or not. The same can be said of the chair left outside the house on the lawn (see the examples given by Pollock, 1888). Similarly, someone who finds a purse of gold and leaves it in his country house while serving a prison sentence a hundred miles away is considered as being in possession until a burglar takes the purse and by this act acquires possession (Bridge, 2002; Holmes, 1881).

Conversely, a person who actually holds the thing may legally not be the possessor. Examples are servants, agents, or employees, who have the use or custody of things but not possession. In a situation where A gives his coat to his servant B to take it to the tailor for alteration, it turns out that although B has physical control, A is still in possession (Pollock, 1888). Similarly, the employee sitting at the office desk using the office computer is legally not considered the possessor of the desk and computer, which remain in the possession of the employer (Bridge, 2002). Under German law, a person resting on a park bench is not considered in possession of the bench. Similarly, a dinner guest is not considered in possession of the chair or the cutlery he uses (Schapp and Schur, 2002; Wolff and Raiser, 1957). Another example is the relationship between landlord and tenant. Under English and German laws a tenant has possession, reflecting the actual occupation and control of the leased property in question; in Roman and French law, a tenant is merely the 'détenteur' and the landlord remains in possession (Nicholas, 1975; Goode, 2004).

Legislation can further complicate these relationships. An insightful example is the *Lien on Wool and Stock Mortgage Act (NSW)* 1843, introduced during the 1843-New South Wales depression and in force until 2005. The Act enabled possession over the wool clip growing on a sheep's back, which was in most instances not yet in existence, to be assigned to the lienee, typically a bank or a merchant advancing funds to the lienor (pastoralist). The lienor retained the actual control of the sheep (Decker, 2008).

Possession of chattels is generally transferred by delivery or taking. Delivery, in contrast to taking, is the voluntary transfer of possession from one person to another. Typically, this requires the physical delivery of the thing. However, in certain situations symbolic delivery is also sufficient. One example is the handing over of possession of the contents of a locked room through the delivery of the keys to the room (Bridge, 2002) or the transfer of timber logs in an open forest by simple agreement (Wolff and Raiser, 1957). Examples of gaining possession by taking include the acquisition of lost or abandoned goods, the capture of wild animals (also referred to as first possession), and the theft of articles by a wrongdoer. Possession of land is transferred by entry or ejectment.

Property law in turn protects possession. It provides the possessor with powerful remedies against any third party who unlawfully interferes with the thing in question as well as in situations where the possessor is dispossessed. In the interest of public peace, this protection is also given to the wrongdoer. Hence a possessor is allowed to exclude third parties and has remedies if dispossessed. Possession, being a property right, also survives the insolvency of the counterparty. For example, if A has leased a vehicle from B, A may retain possession for the duration of the agreement even if B goes into liquidation (Goode, 2004; Bridge, 2002).

Ownership

'Ownership' is one English term for 'dominium' (with 'property' being another term). It is a concept based on Roman property law, with 'dominium' reflecting the complete command that the head of the Roman household, the paterfamilias, wielded over its members (his wife and children) and its property (which included slaves). It encompassed unfettered power over life and death.

Consequently, ownership represents the 'greatest possible interest in a thing which a mature system of law recognizes' (Honore, 1961: p. 108), providing the owner with, for example, the power of occupation and use; the ability to exclude others; consumption; the right to the fruits and profit; destruction; free disposition through sale, gift and exchange; and the burdening of the thing through the granting of security rights (see below) and servitudes to others (Wolff and Raiser, 1957). Servitudes are property rights including rights of way and water, rights of light and support for buildings, and usufruct, being the right to take the fruits and profits from someone's property (Nicholas, 1975; Wolff and Raiser, 1957).

Considerable complexity is introduced by the fact that ownership as the fullest possible interest in a thing includes possession. Hence, as far as exclusive occupation, use and control, and the protection from interference by others are concerned, an owner who is also a possessor is in a similar position to the mere possessor (Holmes, 1881). However, the essence of ownership is not the exclusivity of use and the protection from interference. As Pollock and Maitland identified a long time ago, the pursuit of a thief by the person whose goods were taken "is an assertion of possession rather than of ownership" (Pollock and Maitland, 1898, Vol. 2. Chapter IV: Ownership and Possession). Consequently, ownership is "the ultimate residual right in a thing" (Nicholas, 1975: p. 154; Goode, 2004), designed so that fractions of the right of ownership such as possession or servitudes can be separated and surrendered to others without surrendering ownership itself. It is this capacity to separate ownership and possession that distinguishes modern credit-based monetary societies from tribal and feudal/socialist systems.

An important case in point is a transaction where the owner has surrendered the possession of a chattel for a period of time or at will (that is, being entitled to its return on request). Under English law such an arrangement is technically referred to as a bailment. Examples are an arrangement where the thing is provided to another person under a lease contract for his use, or where the thing is delivered to a creditor as security for a loan under a security arrangement. In both situations, ownership is retained, and the owner has remedies against third parties even though he is not in possession and has also parted with the immediate right to possession for the period of the contract. For example, if the bailee B in breach of contract sells the thing to a third party C, the owner A (bailor) can proceed against C (Pollock and Maitland, 1898; Bridge, 2002).

The critical point is that ownership allows possession to be transferred to other parties while legal rights against the (nonowner) possessor and against third parties interfering with the thing are retained. This separation of ownership and possession in turn enables the operations of a credit-based economy, which could not function without leases, the taking of nonpossessory loan security (see below) and the reservation of ownership over goods supplied but not yet fully paid (Bridge, 2002).

Proof of ownership without possession is difficult. Two important methods of assisting proof are prescription, which requires only possession and the lapse of time ('usucapio'), and registration of title in a public register (Nicholas, 1975). In Roman law a possessor could become the owner of a thing by 'usucapio,' if he, subject to a series of conditions, had had possession of the thing for a period of time. This was set at 2 years for land and 1 year for movables (Nicholas, 1975; Kaser, 1981). Modern societies based on property rights have developed effective registration systems. Ownership and any transfer of ownership are documented in public registers, of which the most important relate to land. Ownership is evidenced by an extract from the register.

Based on Karl Marx's analysis (Marx, 1867), it has become commonplace to contrast private ownership ('Privateigentum') and collective ownership ('gesellschaftliches kollektives Eigentum'). Care has to be taken when using these concepts. Legally, private ownership implies that an individual can hold and exercise ownership rights. In Roman times, those individuals would be the paterfamilias, and in societies with common or civil law systems any person (including corporations) with sufficient legal capacity to enter into contracts. In contrast, collective ownership of a thing within an ownership-based society refers to state ownership, a situation where the right of ownership is held by the state or a government agency (Wolff and Raiser, 1957). However, Marx and Engels envisioned the abolition of ownership altogether and its replacement with the 'collective *use* of all means of production and the distribution of all goods according to joint agreement' (Engels, 1914: p. 71, emphasis added). Hence, their primary concept is possession in the sense of physical control instead of ownership as the basis of relations between creditors and debtors.

Security

Any lender must ensure that loan losses will not exceed the lender's capital, even in unlikely events. One way to contain this exposure and to equalize the risk between lender and borrower is the taking of security (Heinsohn and Steiger, 2013, *see* Security: Commercial Transactions). Security fulfills two purposes. First, it enables the lender to more quickly recoup the amounts owed if the borrower fails to make repayments of loan principal and interest according to the terms of the loan contract. Second, as a property right rather then a mere contractual right, it provides protection to the lender against

competing claims of other unsecured creditors on the borrower's insolvency (McCracken and Everett, 2004). For example, A holds a hypothec over B's land as security for a loan. If B becomes insolvent, A is entitled to have recourse to the hypothecated assets, which are not available to the unsecured creditors. This is because A's right represents a relationship with the asset (thing) taken as security and not only a contractual relationship with the insolvent debtor B.

The taking of security has a long history. It is well evidenced in ancient Greece (Finley, 1951; Harrison, 1968) and was fully developed and codified in Roman law (Kaser, 1981). Security rights can be classified as possessory and nonpossessory. The most important possessory security right is the pledge (Roman 'pignus'). Here the borrower delivers the thing used as security to the lender. The lender acquires possession but the borrower retains ownership. Should the borrower default, the lender has the right to sell the thing, discharging all or part of the obligation with the sale proceeds.

In contrast, nonpossessory security rights are those that leave the possession of the thing used as security (also referred to as loan collateral) with the borrower. These are economically the most important as the borrower can raise funds from a lender and can continue with the occupation and use of his things, which are typically production assets (Decker, 2013). Nonpossessory security rights can be implemented in two ways. First, the borrower retains possession but transfers the ownership of the thing taken as security to the lender under an agreement to reconvey ownership on performance of the loan contract. The transfer of ownership provides the lender with the powers and rights of an owner, subject to legal restrictions and the terms of the loan agreement. Most importantly, ownership confers the power to sell the hypothecated asset if the terms of the loan agreement have been breached. Examples of this type of security right are the Roman law 'fiducia' (Kaser, 1981; Nicholas, 1975); the legal mortgage under English law (where possession may be transferred back to the borrower) and the security transfer ('Sicherheitsübertragung') for chattels in German law (Wolff and Raiser, 1957). Second, the borrower retains ownership and possession but the lender is provided with a 'charge' against the thing taken as security. The charge provides the lender with the powers specified in the loan agreement, typically the power to insure, the power to appoint a receiver and the power to sell (McCracken and Everett, 2004). Examples of this type of security are the pledge without possession, 'pignus obligatum' or 'hypotheca' in Roman law (Kaser, 1981; Nicholas, 1975), the equitable charge (including the fixed and floating charge) under English law and the 'Hypothek' under German law (Wolff and Raiser, 1957).

Nonpossessory security rights are often documented in public registers that identify the thing subject to the security arrangement. Examples are land, ships, motorcars, cattle, and wool. Registration often helps to regulate the priority of claims and allows other creditors to assess whether there are existing claims against the borrower's assets in question. As far back as ancient Greece, the registration of security rights was known. It was customary to place a mortgage stone ('horos') on the land inscribed with the particulars of the loan. Approximately 250 'horoi' have been found and documented (Millet, 1985).

Security rights play a critical economic role as the creation of money relies on the ability to encumber property by way of security for loans (*see* article Property Ownership and Heinsohn and Steiger, 2013). Central bank money is created when commercial banks enter into a loan contract with the central bank that must be secured by eligible central bank collateral. Furthermore, the function of the central bank as the lender of last resort is based on security rights. The underlying principle is that anyone able to furnish sound loan security must be able to obtain liquid central bank funds in a crisis (Heinsohn and Steiger, 2013). In turn, commercial banks create deposits through loans, the majority of which are directly or indirectly secured by land, houses, ships, cars, cattle, agricultural products or plant, and equipment.

Historical Development

Humans have been organized in tribal communities for the majority of human history. It has been estimated that communities of hunters and gatherers account for 90% of that period (Lee and Daly, 2005). Anthropological studies confirm that tribal communities knew a form of possession protected by force or customary rules. There is evidence that tribes laid exclusive claims to territories that were defended against intruders. Land could be allotted to a family household who had a use right; game that had been killed and left lying to be fetched later was marked with branches as tabu signs; and the manufacture of articles created a personal claim to their possession (Sahlins, 1974; Thurnwald, 1932). However, the difference between possession and ownership as used in the context of creditor and debtor, that is, the "distinction between the actual holding of a thing and the legal claim to it […] is unknown" (Thurnwald, 1932: p. 192). Or, as the eminent anthropologist Malinowski notes, the "term 'own' as we use it is meaningless, when applied to a native society" (Malinowski, 1922: p. 117). Consequently, while a form of possession is known, ownership as a residual right exercised independently of possession is unknown to tribal communities and therefore is unlikely to have played a role throughout most of human history.

Another dominant form of social organization throughout history has been command systems such as Mycenaean Greece, the Inca Empire, the medieval European feudal seigneuries and state socialism. Command systems are organized through coercive mechanisms where a ruling class extracts dues and services from serfs or serflike workers (Heinsohn and Steiger, 2013). As in the case of tribal communities, it has been observed that property law in command systems – if one can use the term – was limited to possession. For example, medieval European feudalism was governed by the concept of 'seisin' (possession, Pollock and Maitland, 1898). Land in feudal systems was held by a sovereign lord and individuals had access and use rights in return for dues and services. To use "the word 'ownership' […] would have been almost meaningless […] [f]or all land and a great many human beings were burdened at this time with a multiplicity of obligations" (Bloch, 1961: pp. 115–116). This is consistent with the fact that the English word 'ownership' is only evidenced as recently as 1583 (Pollock and Maitland, 1898), a time when England was no longer a feudal society and its transition to an ownership-based economy governed by relations between creditors and

debtors was well underway. The notion of possession as the leading concept also holds true in relation to the treatment of chattels in medieval law. It has been noted that the "punishment of thieves and the restoration of chattels to those from whom they have been stolen were the main objects which the law had set itself to attain" (Pollock and Maitland, 1898, Vol. 2. Chapter IV: Ownership and Possession). In relation to the lord, the serf was without formal rights. An English lord might beat or imprison his serf, seize his chattels, and eject him at his discretion (Pollock and Maitland, 1898; Lipson, 1956). The serf was also unprotected against the world at large. If a third party ejected him, it was the lord who was considered disseised (dispossessed) (Pollock and Maitland, 1898).

There also exists no right of ownership in the former and failed system of state socialism with its system of central planning, although the term 'ownership' was used. While use rights were allocated to individuals over, for example, rural land, these were not full ownership rights, but limited rights stripped of essential powers such as the right to divide, sell, lease, or hypothecate the land. Consequently, the German Federal Court in a landmark dispute over land rights granted by the former socialist authorities in East Germany concluded that these socialist use rights no longer fulfilled the essential meaning of ownership according to the German civil code (Heinsohn and Steiger, 2013).

The situation regarding the ancient economies of Greece and Rome (1000 BC–AD 500, Finley, 1973) is very different. It is within those economies that property rights and a concept of ownership as separate from possession in the modern sense are believed to have originated (Pipes, 1999; there is also some evidence from Mesopotamia, see Westbrook, 2003; Heinsohn, 1984) and within which private ownership became the characteristic feature of social organization (Finley, 1973). In Greece, the property law of Athens recognized the distinction between ownership and possession. There is a strong body of evidence confirming the existence of security rights, including those rights that left possession of the collateral with the debtor. One example was the most common form of real security, 'prasis epi lysei' (sale subject to redemption, Finley, 1951). Evidence in texts is confirmed and supplemented by numerous mortgage stones (Harrison, 1968; Millett, 1985).

It was, however, the Romans who developed property law into 'an elaborated articulated system of principles' (Nicholas, 1975: p. 1), providing mankind for the first time with a fully fledged system of property rights, including ownership as a right distinct from possession and security rights encompassing nonpossessory rights such as the hypothec. In turn, Roman law became the model for property law systems in Europe, forming the basis of the French civil code (Code Napoléon of 1804) and the German civil code of 1896 (Nicholas, 1975). An exception perhaps is England, which has retained its own common law. Yet even the development of the common law was not without Roman law influence. Most legal systems currently operating in the world are directly or indirectly derived either from English common law, French civil law, or German civil law (Berkowitz et al., 2003).

How did the right of ownership first emerge? This is a topic of considerable uncertainty. The Bronze Age, with its feudal command systems such as the Mycenaean civilization, is reported to have come to a rather abrupt end with archaeological evidence revealing cataclysms resulting in the widespread destruction of palaces and fortress complexes (Finley, 1981; Welwei, 1983). Invasions and large-scale natural disasters have been considered as possible causes (Finley, 1981; Welwei, 1983; Heinsohn, 1984). In Greece, a completely new society was then built by those who remained (Finley, 1981). Hence, it has been argued (Heinsohn, 1984) that the emergence of societies based on ownership, like the Roman civitas and the Greek polis, was not a gradual evolutionary process but was triggered by exceptional historical circumstances. In the wake of natural disasters, revolutionaries such as the legendary Greek hero Theseus, who is reported to have promised a new society – a 'government without a king' (Plutarch) – overturned their feudal rulers and established a free society based on the distribution of former feudal land holdings to their members. According to Varro, Romulus – the legendary founder of Rome – allotted an equal amount of land (the 'heredium') to each citizen. This created, for the first time, a society based on private ownership of land (*see* article Property Ownership) (Heinsohn, 1984; Heinsohn and Steiger, 2013). The societies created in this way were in sharp contrast to feudal societies as they were regulated not by rules of command but instead by relationships between creditors and debtors, who were bound by property law and who sold, mortgaged, and leased their assets. At the same time, the newly formed ownership-based societies became the birthplace of freedom and democracy (Pipes, 1999; Steiger, 2005). At a more general level, it has been argued that tribal, command and ownership-based systems represent three distinct archetypes of human organization, which impose radically different rules of production, distribution, consumption, and accumulation. In contrast to possession, ownership is only present in one of the three systems (Heinsohn and Steiger, 2013; Steiger, 2006).

The fall of the Roman Empire ended the relatively short regime of ownership-based systems. It was not until the fourteenth century that a new type of ownership-based society began to reemerge on a significant scale in England. In the mid-fourteenth century the demographic disaster of the Black Death swept away substantial parts of the European population. Demographic changes of this magnitude weakened and undermined the existing social structures throughout Europe. The reaction was either a tightening (Eastern Europe) or a disintegration (Western Europe) of feudal structures (Brenner, 1976). England, whose population decline from the Black Death (1348/49) has been estimated at 30–50% and which experienced a violent and widespread peasant rebellion in 1381, witnessed a complete disintegration of the old feudal order within a century of the Black Death (Lipson, 1956). With labor scarce and the position of peasants strengthened, English landlords could no longer rely on compulsory labor services to cultivate their demesne (the portion of the seigneurie, where the product was taken directly by the lord). Having lost their serf-labor while retaining the land, landlords began to rent out their demesne to substantial tenants who could sublet the land. In addition, the service obligations owed by serfs were commuted to money rents and traditional holdings – providing unlimited use rights when the tenure was hereditary – were converted into shorter term leases when an opportunity arose (Wrightson, 2002). This allowed landlords to commence the economic management not only of their demesne, but also the rest of the seigneurie after evicting customary tenants (Nabholz, 1941).

The introduction of widespread tenant farming raised the legal question of who had possession: the lord or the tenant/leaseholder (lessee). The answer, already developed in the early thirteenth century, was the 'theory of double seisin' (Pollock, 1888: p. 48). The "lessee had a kind of seisin and yet the lessor [lord] did not lose the seisin which he had before" (Pollock, 1888: p. 49). It subsequently became customary to confine the term seisin to the lord's right over his holdings and the Roman term 'possession' was introduced as a technical term to describe the seisin of the land exercised by the lessee, who occupied the land. The lessee, unlike the medieval serf, had now possessory rights against third parties. This development was paralleled by the evolution of bailment of chattel property. When bailment became more important, the bailor acquired rights against third parties and not just against the bailee (Pollock and Maitland, 1898). Hence, a conceptual separation analogous to that of ownership and possession was recreated in English common law underpinning the reemergence of an ownership-based economic system built on tenant farming, which transformed England into the leading economic power of the world (*see* article Property Ownership).

In line with the transformation and success of the English economy, English property law was transplanted in the colonies of the British Empire. As part of this process, former aboriginal land was distributed on a vast scale to European settlers through purchase or land grants to companies and individuals. In addition, schemes to distribute public lands in the colonies – not dissimilar to the original land distribution attributed to Romulus – were set up. Land was granted to any eligible individual, subject to occupancy and improvement conditions and either for free (for example, the United States Homestead Act of 1862 and the Canadian Dominium Lands Act of 1872) or on generous credit terms (for example, the New South Wales Crown Lands Alienation Act 1861 and the Victorian Lands Act of 1862). From the first half of the nineteenth century, many countries introduced major property and land reforms to modernize their economies in order to keep up with the developments in England. Prominent examples are the Stein–Hardenberg reforms of 1807 in Prussia, the 1861-emancipation edict by Tsar Alexander II, and the reforms in Japan under the Emperor Meiji in the second half of the nineteenth century. In 2007, China, the country with the world's largest population, introduced the Property Law of the People's Republic of China, formalizing a development path taken by England six centuries earlier (Heinsohn and Steiger, 2013; Steiger, 2006).

Prophetism

Malcolm Hamilton, University of Reading, Reading, UK

Abstract

This article examines the phenomenon of prophetism that occurs widely in many religious traditions and cultures in many periods of their history. After discussing the nature and definition of prophetism and of the central figure in prophetic currents and movements – the prophet – the article traces the sociological foundations of the concept in the work of Max Weber and his stress on the charismatic nature of prophecy. The way Weber differentiated between prophets and other religious specialists is discussed. Weber's analysis of Biblical prophecy is then examined followed by a discussion of later critiques of Weber and of recent work on Biblical prophecy. The article concludes with an examination of the role of the prophet in religious movements, and in particular millennial movements.

Prophetism may be defined as a religious current or movement promoted by the activities of a prophet. A prophet in turn may be defined as a leader of or key participant in a movement or group who proclaims a religious mission on the basis of personal revelation. While many prophets have been founders of religious movements they are not necessarily so but may be significant figures within a revitalization of a religious group or simply play a central role in the religious life of a group or community by pronouncing upon religious matters through revelatory insights or experiences. Neither is the foretelling of future events a necessary component of prophecy but is not uncommonly associated with it. A prophet may or may not convey a message from the gods or be the mouthpiece of divinity. They may express the word of God or the gods or may simply convey religious truths to their followers, which are not claimed to stem from such supernatural sources. Buss (1980) puts the point usefully in the following terms: 'The role of a prophet or seer can be characterised as the receiving and transmitting of communications not available to ordinary conscious sensitivity which are held to come from a source (the divine) or through a form of perception transcending normal spatio-temporal limitations.' Prophets may or may not claim spiritual or supernatural powers themselves and may or may not receive revelation through the experience of states of trance or possession.

What is essential to the notion of prophecy, then, is the relatively emotional proclamation of a religious message that has been revealed personally in a nonroutine and non-mundane manner. Prophets are called to their mission and compelled to follow it whether voluntarily or, as is not uncommon, very reluctantly.

The category of prophet as a religious specialist or type of religious figure is one which owes much to Weber who gives it a central role in his sociology of religion (see Religion, Sociology of). For Weber a prophet is 'a purely individual bearer of charisma, who by virtue of his mission proclaims a religious doctrine or divine commandment' (1965). Weber distinguishes the prophet from the category of priest. The priest commands religious authority on the basis of a position within a sacred tradition or religious organization and dispenses salvation by virtue of holding an office while the prophet commands religious authority on the basis of personal charisma and recognition of a personal calling to a mission through revelation. The term 'charisma' is used by Weber to refer generally to extraordinary powers essentially of a magical or non-mundane nature (see Charisma and Charismatic). The priest for Weber is thus the upholder and guardian of tradition while the prophet is a religious innovator or at least a radical revitalising force.

Weber is careful to distinguish the prophet from a number of other types of religious specialist. While the authority and following of prophets may be based upon magical charisma they are not primarily magicians or workers of miracles. The prophet is concerned primarily with doctrine and commandment. It is this that distinguishes the prophet from the mystagogue whose following is based purely upon attribution of magical powers. Yet it is rare that prophets are not expected to give proof of their particular gifts and such proof has more often than not taken the form of possession of magical abilities. Reflecting the fact that charisma may be either inherent or acquired through undergoing extraordinary experiences or practices, these capacities may be inherent in the person or may be acquired through, e.g., ascetic regimes or cultivation of ecstatic states.

Again, while prophets engage, in many instances, in divinatory activities, as was the case, e.g., with the Biblical *nebiim* (singular *nabi*), they may be distinguished from diviners on the basis that it is normal for the latter to be economically recompensed for their services. Prophets provide their spiritual revelations gratuitously and, indeed, often unbidden. To do otherwise would be to undermine their distinctive claim to religious and spiritual influence.

Likewise, Weber distinguishes the prophet from related or similar religious specialists such as legislators, arbitrators, social reformers, orators and teachers on the grounds that lacking in the case of all of them is the proclamation of a religious truth on the basis of personal revelation. Later usages of the term 'prophet' are often less precise and looser than Weber's but in general at the root of them is this specific emphasis upon a purely personal revelatory impulse and calling.

Weber distinguished between two fundamentally different types of prophecy. In the 'ethical' or 'emissary' type, exemplified most clearly by figures such as Zoroaster or Muhammad, the prophet is an instrument for the proclamation of the message or commandments of a god. The doctrines proclaimed by such a prophet take the form of ethical duties. In the

'exemplary' type, most clearly exemplified by the Buddha, the prophet proclaims a soteriological message by personal example and demonstration of the means or path to salvation which others are free to follow to their personal benefit if they wish or ignore to their personal detriment.

In both cases the prophetic revelation acts to promote a meaningful understanding of life in relation to the whole of reality to which conduct must be brought into alignment if salvation is to be attained. It involves the construction of a cosmos as a meaningfully ordered totality. As Parsons (1965) says 'the prophet is above all the agent of the process of breakthrough to a higher, in the sense of more rationalised and systematised, cultural order, an order at the level of religious ethics, which in turn has implications for the nature of the society in which it becomes institutionalised.' While there is such a stress in Weber's characterization of the prophet upon the construction of a more rationalized and systematized meaningful order, prophecy, Parsons is careful to point out, is not fundamentally an intellectual or theological enterprise but frequently takes emotional and sometimes even violent forms.

Weber's most extensive analysis of specific prophetic activity and prophetic movements occurs in his study of the development of Judaism, in his *Ancient Judaism* (1952), a development in which the Biblical prophets are given a crucial role (see Judaism). Weber traces the emergence of a new type of prophet towards the end of the period of the confederacy that he distinguishes from the earlier ecstatics or *nebiim* and the *roeh* or oracle givers. These new prophets saw themselves as called upon to transmit the will of Yahweh to the people and to the rulers. Early prophets of this type did not pronounce unless solicited but progressively they spoke independently and increasingly critically of the political authorities. From the time of Elijah onwards prophets spoke as much to the masses as to the rulers culminating in a situation in which the prophets became the intellectual leaders of the opposition against all that monarchy was perceived to stand for – centralization of power and government, heavy taxation, and social injustice.

Not that Weber considered social justice to be their primary concern. It was the destiny of the state and of the people that motivated their essentially religious yet inextricably political message. It was their purely religious concerns with fulfilling the commandments of Yahweh that brought upon them the opposition of the authorities. For Weber the Biblical prophets represented the values and ethos of the presettlement confederacy.

Classical Biblical prophecy in Weber's analysis is characterized by independence, spontaneity, and disregard for popularity among any sector of Israelite society. It was indifferent to economic, material, or other reward in contrast to other types dependent for their livelihood upon prophecy and prediction. They were at best tolerated and not infrequently persecuted.

While not primarily diviners and seers the classical Biblical prophets nevertheless stressed the dire fate that Israel would suffer if it did not keep the terms of its covenant with God. Such was the precarious situation of the Israelite states in Palestine that gloomy predictions were not uncommonly fulfilled. The religious conduct of the Israelite people was linked intimately by the activities of the prophets to their material and political fate and to that of the state.

The conditions which promoted the development and impact of prophetic currents of this type were those of military and political insecurity and unpredictability. Weber considers that new religious insights rarely occur in the main centers of civilization but rather in areas on their periphery which are subject to their influence and pressure. Those who live in such regions repeatedly are given reason to question the meaning of events that affect them. Unlike the inhabitants of long stable, politically secure, and settled regions who tend to take the world for granted, those outside these areas constantly are puzzled by the turn of events; 'the possibility of questioning the meaning of the world presupposes the capacity to be astonished about the course of events' (Weber, 1952).

Subsequent research on Biblical prophecy has often been critical of aspects of Weber's analysis and by implication of his analysis of prophecy and prophetism in general. Berger (1963) and Turner (1974) have questioned whether the Biblical prophets were the independent force based upon pure charismatic authority and motivated entirely by religious concerns that Weber portrays them as being. In fact, the classical Biblical prophets are more likely, according to some recent research, to have occupied official positions in the cult of Yahweh. The conclusion that writers such as Turner draw from this, that it requires us to reconsider Weber's understanding of prophetic charisma as an autonomous and personal force and to recognize that it arises from the incumbency of positions in an established social institution is, perhaps, rather extreme. It is likely that there were several different types of prophet in ancient Israelite society. Emmet (1956), who considers that Weber equates prophecy with charismatic authority which she finds too restrictive, usefully differentiates a number of types of prophet. First, there is the institutional prophet who fulfils a traditional and established role. Second, corresponding to Weber's charismatic prophecy, there is the leader of a movement which seeks radical change. Finally, there are prophets who do not attract a personal following but who act as independent critics, advocates of reform or who provide moral leadership. While the prophets associated with the Temple in Jerusalem, whose function was an institutionalized one within the Temple cult, were perhaps more numerous, the classical Biblical prophets with which Weber was concerned may be considered to be of a different type. Whether they enjoyed greater autonomy and independence stemming from personal charisma is still, however, open to question.

Weber's stress upon the charismatic authority of the classical Biblical prophets has been challenged by Petersen (1979) on the grounds that there is no evidence that they were leaders with a group of followers, which he claims is implied by Weber's notion of charismatic authority. Neither is it useful, in his view, to characterize Biblical prophets as office holders. The dichotomy between charismatic leader and office holder is, in any case, he argues, far too strictly drawn. We are led, therefore, to question whether the Israelite prophets could have provided the breakthrough that Weber attributes to them. In a later work Petersen (1981) argues that we may get a better understanding of the Biblical prophets if we see them as having a specific role. He applies role theory in an analysis of their position in Israelite society based upon a close examination of the use of a variety of terms in Hebrew used to refer to such figures. The results show that there was more than one type of prophetic

role in this society. Some held established positions in the official cult and operated also by offering a personal service for a fee. Others, termed central morality prophets, pronounced as individuals at times of crisis but in order to uphold established values and institutions. Still others, peripheral prophets, operated outside institutional contexts and established values.

Also doubtful of the simple dichotomy of functionary versus autonomous charismatic is Lang (1983). The prophetic tradition, he argues, was largely an institution of the land-owning nobility that enabled them to express publicly their political views. He attempts to show that the prophets were largely from a land-owning, noble background. While they were not chosen by formal procedures but simply emerged, they nevertheless, according to Lang, had to learn how to be an acceptable prophet and to observe the rules governing appropriate behavior for prophets. They were closer, however, to Emmet's third type, in Lang's view, and not wholly established functionaries within the cult. The contrast between charisma and tradition in discussions of prophetism is indeed often overstated. Lang points out that they are often bound up with one another in complex ways such that prophetic charisma can be seen as a force for renewal which emerges within traditional structures at certain times. It is a force that changes and reforms without destroying.

While the Weberian view of Biblical prophecy has, in recent decades, been questioned by some, it has for others stood the test of time and deeper scrutiny rather more robustly. Williams' analysis of sources (1969), e.g., supports the view that many of the classical prophets were independent of the official cult. A detailed study by Wilson (1980) is alert to the complexities and differences between periods and regions. He contrasts the premonarchical Ephraite tradition of the North with the monarchical period in both the Northern and Southern kingdoms and also different periods and circumstances in the South. In the premonarchical North, prophetic behavior was expected to conform to familiar patterns regarding the stereotypical linguistic style in which pronouncements were made and to customary behavioral patterns. This clearly suggests that these prophets occupied a defined position and role within the central religious institutions of the society. In the monarchical period prophets seem to have become figures of less central significance but rather more peripheral to the established religious institutions and rather more concerned with producing change. In Judah, however, political circumstances and alliances differentially affected the type of role and significance that prophets had. Some, standing outside the established cult, were more critical of the status quo while others exercised a more supportive function. This reminds us that prophetism, at least of this type and in these circumstances, may not simply refer to a movement or development led by a prophetic figure but to a dynamic situation of struggle to define or lay claim to the accepted interpretation of a religious tradition or interpretation. Lang (1983) points out that, like many prophets in various traditions and cultures, Jeremiah engaged in conflict with rival prophets opposed to his policy of accommodation with the Babylonians and who advocated total resistance.

Such debates highlight the extent to which Biblical prophecy, and it is an observation applicable to all prophecy, is associated with crises which, while differing extensively in kind, generally call forth a questioning of the status quo and of established institutions and patterns of power and authority. This point has been made by Carroll (1979) in the case of ancient Palestine and Weber's analysis. The religious-political factions that tend to emerge in such circumstances may understandably become aligned with pro-regime and anti-regime types of prophecy.

Not that this necessarily means that prophetism is really a form of politics under the guise of religion. As Albrektson (1972) notes, Weber may well be correct in attributing to the Biblical prophets motives which were primarily religious. Circumstances often made their pronouncements political in tone but at root they were essentially utopian and idealistic rather than pragmatic or designed to stir up political opposition for its own sake.

The political element in prophetism is a factor that comes to the fore most notably in studies of those forms of prophetism that can be described as millennial. It is in the context of the quite extensive studies of such movements that prophetism has been most systematically examined (see Millennialism). Not all prophetic movements are millennial and not all millennial movements are prophetic, though most are. It is prophetic millennial movements, however, that have received most attention (see, e.g., Wilson, 1975). The role of the prophet in millennial movements varies. Such movements may be initiated by the visions, revelations, and activities of a prophet. Once underway they may call forth a prophet who focuses relatively disordered and uncoordinated activities of participants and who gives coherent expression to previously vague, inchoate, and diverse ideas. The appearance of the prophet transforms millennial ferment into a millennial movement.

The role of the prophet in the millennial movement generally has been found to reflect Weber's emphasis upon prophetism being associated with social and political crisis or radical social change. On the other hand, it is rarely a complete break with the past and more often a process of bridging past and present, the traditional and the new. The prophetic message in such movements tends to reinterpret old understandings in ways appropriate for an altered situation while at the same time adding new elements and opening up the imagination to new possibilities. The prophet gives concrete expression to what are often inarticulate feelings and ideas and channels them into a program of action promising redemption from current ills. The prophet helps those who are confused by circumstances of change, uncertainty, and instability to comprehend and grasp the meaning of their situation by offering insight derived from special revelation which through understanding points the way forward for remedying what is unsatisfactory. Prophetic movements frequently are found in circumstances of disaffection in which a population is subject to foreign or colonial rule or have little comprehension of the mechanisms and structures of power or how to operate within them in order to ameliorate their situation. The prophet provides the missing knowledge and means of finding solutions. It is significant that many prophetic leaders of such movements are more knowledgeable than their followers as a result of wider experience through travel, limited education, or access to information. The prophet, by providing a focus, is often able to bring together otherwise fragmented communities and diverse groups previously unable to operate in

concert in the pursuit of common aims. What is promised, however, is not simply material but also usually, and more significantly, moral and emotional redemption through the recovery of lost personal and cultural dignity and sense of self-worth.

Prophylaxis in Psychiatry

David Castle, University of Melbourne, Melbourne, VIC, Australia

© 2015 Elsevier Ltd. All rights reserved.

This article is a revision of the previous edition article by J. Levine, S. Gershon, volume 18, pp. 12212–12216, © 2001, Elsevier Ltd.

Abstract

Prophylaxis in psychiatry can be considered as a series of phase-specific constructs, targeting different stages of mental illnesses. Types of intervention encompass medications as well as broader psychological and psychosocial constructs. In this article, we discuss three psychiatric disorders as illustrations of the different prophylactic paradigms; these disorders are schizophrenia, bipolar disorder, and major depression. We then address the important aspect of physical health problems – notably cardiovascular issues such as obesity, diabetes, and hypercholesterolemia – that are often associated with major mental illnesses and which may be compounded by certain psychiatric medications. Finally, we provide an overview of issues pertinent to adherence to treatment interventions.

Schizophrenia

Schizophrenia is a disorder that appears to have its origins in abnormal neurodevelopment, albeit it usually manifests in terms of 'obvious' symptoms such as delusions (false beliefs) and hallucinations (abnormal perceptions), collectively called 'positive symptoms,' in the late teens in males and early to late 1920s in females (Castle et al., 1998). The major known risk factors for schizophrenia are genetic, with a complex polygenetic multifactorial inheritance compounded by epigenetic and gene–environment interaction effects. Known 'environmental' risk factors include maternal exposure to influenza type A and (possibly) toxoplasmosis; maternal starvation, anemia, and low vitamin D levels; and pregnancy and birth complications (Castle and Buckley, 2015). There is also evidence that cannabis consumption in the teens can increase the likelihood of later schizophrenia. The problem with any of these factors as targets for preventing schizophrenia is their low associated risk (mostly of the order of a twofold increase in risk) and their lack of specificity. This is not to say that attempting to reduce such risk factors is a bad idea, but simply that the 'yield' at a population level is likely to be low. For example, it has been estimated that the population attributable risk of cannabis in schizophrenia is of the order of 8% (Arseneault et al., 2004), suggesting that elimination of cannabis from the face of the globe would reduce the incidence of schizophrenia by around 8%; not a trivial amount, but small in terms of return for such a massive endeavor.

A more parsimonious approach could be to target women at high genetic risk for having a child with schizophrenia (e.g., if she has schizophrenia herself) and offering them the very best in obstetric and perinatal care. All of the maternal risk factors quoted above could be addressed, as well as the drug and alcohol consumption which is all too often associated with schizophrenia and which can also impact the developing brain. Assisting the mother to bond with her infant could also assist, expressly as affective expression is often limited in people with schizophrenia. Such approaches have the challenge that many pregnant women with schizophrenia are suspicious of and avoid health services, often through fear of having their baby removed from them (Hearle and McGrath, 2000).

As already stated, schizophrenia usually only manifests itself definitively in later adolescence or older, but certain 'markers' might be evident even in childhood. These include delays in language acquisition and motor milestones, as well as impairments in socialization. However, any such factors are very nonspecific and most children with such 'markers' do not develop schizophrenia, making them an impossible target for preventative interventions. However, there has been increasing interest in whether certain individuals at supposed 'ultra high risk (UHR)' for the disorder might be effectively identified and offered prophylactic treatment. Various approaches to determining UHR status have been researched, but most include some combination of psychotic symptoms, such as paranoia or grandiosity that do not reach the intensity required to meet diagnostic criteria for the disorder as such; brief limited psychotic episodes or BLIPS; and having a family history of schizophrenia or schizotypy and showing psychosocial decline. Initial studies were very promising in the sense that around 40% of people identified in high-risk specialist services who met such criteria 'transitioned' to full psychosis. However, more recent studies using broader sampling frames have had a much lower yield (of the order of 8–10%) (Fusar-Poli et al., 2014). Extrapolation to a general population shows that in individuals who are not 'help-seeking,' the positive predictive value of putative UHR-like symptoms is very low (around 1%) (Werbeloff et al., 2012). A major problem for this approach is the lack of specificity of such symptoms (psychosis-like symptoms occur in 10–15% of the population) and also the lack of specificity of potential outcomes (people with such symptoms are also at higher risk of developing mental disorders other than schizophrenia).

The refinement of the UHR approach, by adding other symptoms and potentially neurobiological markers for schizophrenia (e.g., Lawrie et al., 1999; Shimushi et al., 2000) is a worthy endeavor, but even if this reaps dividends in terms of enhancing the positive predictive value, there remains a question as to what prophylactic interventions could be offered to prevent 'transition' to a psychotic illness. A number of approaches have been tested, including antipsychotic medication and cognitive behavior psychotherapy or combinations thereof, but unfortunately the more recent,

methodologically robust studies have largely been negative (Castle, 2012). One very intriguing study showed a dramatic effect for the simple intervention of fish oil (omega-3 fatty acid) for 3 months, but this study has not been replicated. In sum, the UHR approach, while potentially very exciting, has thus far not delivered on its early promise. No specific intervention can at this stage be recommended, and most clinicians would eschew exposing putative UHR individuals to antipsychotic medications, expressly in light of the side effects associated with such agents (see Section Physical Health Prophylaxis in Psychiatry). Psychological interventions do hold some promise, not so much in preventing transition to psychotic illness, but in helping the individual deal with distressing symptoms.

Moving on from the UHR approach, there has been worldwide interest and excitement about the potential for early intervention using a series of established treatments (including antipsychotic medications, psychological treatments such as cognitive behavior therapy and family treatment) in ameliorating the long-term course of schizophrenia. Part of this approach has been to try to reduce the so-called 'duration of untreated psychosis (DUP),' as longer DUP has been associated with worse outcomes in schizophrenia. A number of trials have suggested that the delivery of comprehensive treatment packages by a specialist team or service can indeed improve some outcomes (e.g., reduced hospitalizations) but the effects are modest as best and largely disappear once the specialist intervention halts (Bosanac et al., 2010). One conclusion is that good treatment is beneficial for schizophrenia irrespective of the phase of illness, and that there is nothing particularly special about the first episode; but other commentators are more generous to the early intervention field, believing that the earlier the intervention, the better the longer-term outcome. Certainly one should not only withhold treatment from people early in the course of an established psychotic illness, but arguably such interventions should be offered to the individual (and their family, where possible) for as long as is required.

Irrespective of the efficacy of otherwise of UHR and early psychosis services, in remains the sad case that many people with schizophrenia continue to relapse and/or experience functional decline and social and vocational dislocation. Maintenance therapy in schizophrenia is provided by long-term treatment. Based on accumulated experience, it was suggested that people with schizophrenia could be looked at as two groups. In first group, maintenance therapy seems to play a 'suppressive role,' and its discontinuation leads to a rapid reappearance of psychotic symptoms. The second putative group comprises individuals in whom the treatment has more of a 'prophylactic' role. In this latter group, discontinuation of treatment leads to a more gradual and remote-in-time recurrence of symptoms (see Gelenberg et al., 1991).

It is estimated that about 10% of remitted medication-free patients with schizophrenia will relapse in any given month. That means that after 6 months, roughly about half of these patients will relapse, whereas after 12 months about 70% will do so, and only a small portion will not relapse at the end of 2 years. Several strategies of maintenance treatment have been suggested for these patients. The first strategy consists of continuous maintenance treatment. This strategy applies relatively lower doses of antipsychotic treatment as compared with that used for acute exacerbation. The second strategy includes 'drug holidays,' that is, treatment periods interrupted by drug-free periods. This strategy was suggested in order to lower the incidence of side effects while retaining drug efficiency. However, such a strategy is not recommended nowadays since research studies could not support its effectiveness. The third strategy suggests 'intermittent' treatment or 'targeted dose' for chronic schizophrenia patients. In this case, patients are treated during the acute episode only, while monitored for the appearance of prodromal symptoms (first symptoms anticipating the appearance of an exacerbation). Once prodromal symptoms appear, pharmacological treatment is initiated. Again, this strategy does not have general support in the literature or clinical practice.

In general, pharmacological treatment in schizophrenia includes the use of a group of drugs collectively called 'antipsychotics.' These drugs have the ability to block neurons using the neurotransmitter dopamine to transmit messages to other neurons (dopamine D2 receptors). While effective for the positive symptoms of schizophrenia, these agents are not terribly effective for the negative symptoms (withdrawal, apathy, restriction of affect) and also tend to cause extrapyramidal side effects (distressing motoric problems such as stiffness, tremor, and severe restlessness) and also raised plasma prolactin.

In the 1980s, a second generation of drugs came into use. The prototype was clozapine (actually introduced initially in the 1970s but withdrawn because of hematological problems in most countries, to be reintroduced in the late 1980s with various safety requirements). Clozapine is a drug that, besides its ability to block some types of dopaminergic receptors, can also exert a blocking effect on certain serotonergic receptors – labeled as 5-HT2 neurons – in the central nervous system. This drug was shown to have a lower side-effect profile compared to the more traditional drugs; especially it has minimal extrapyramidal side effects and does not elevate plasma levels of prolactin. However, clozapine also has several distressing side effects including the lowering of white blood cell count that may expose these subjects to severe infections; myocarditis and cardiomyopathy, weight gain and diabetes, and profound sedation, to name a few. Clozapine seems to ameliorate not only the positive illness symptoms, but also the negative symptoms of schizophrenia (a set of symptoms characterized by impaired volition and motivation, apathy, and paucity of speech), and it may also improve some neurocognitive impairments demonstrated in this disease (see Kane et al., 1988).

Beside clozapine, other second-generation or 'atypical' antipsychotic drugs have also been developed, including risperidone, olanzapine, quetiapine, paliperidone, and lurasidone. Other atypical antipsychotics with unique mechanisms of action are amisulpride (a selective dopamine D2/3 blocker) and aripiprazole (a partial D2 antagonist). There has been much debate about whether these newer agents are truly more effective or better tolerated than the older (and much cheaper!) typical drugs, but most Western countries have embraced them and they have become the mainstays of prevention of relapse in people with schizophrenia (Castle et al., 2013). A number of problems remain, however, including side effects such as weight gain and diabetes with some of these agents (see Section Physical Health Prophylaxis in Psychiatry) as well as problems with medication adherence (addressed below).

Also, it goes without saying that medications are not the sole effective interventions for people with schizophrenia; indeed, an holistic multidisciplinary approach dealing with psychological, vocational, and family issues is required to achieve the best outcomes for people with schizophrenia. This is also consonant with the so-called 'Recovery Movement,' which aims to empower people with a mental illness gain better control over their lives in a broader sense, beyond simply focusing on symptoms of illness. A number of innovative interventions are trying to deliver on this: some include using people with the 'lived experience' of mental illness to act as peer support workers. A particular additional issue in many jurisdictions is that people with schizophrenia use illicit substances to excess, and there is good evidence that this is associated with worse outcomes and more relapses; again, concerted attempts are required to engage people with schizophrenia in reducing such harmful drug use.

Maintenance in Bipolar Illness

Bipolar disorder is characterized by the appearance of manic episodes with or without the occurrence of depressive episodes. It is estimated that the majority of patients who had a manic episode will have one or more recurrences. Since both manic and depressive episodes may be associated with progressive deterioration of interpersonal and occupational functioning, and may also carry the risk of harming oneself or others, an adequate maintenance treatment for bipolar illness is of utmost importance.

In terms of medication, several mood stabilizers – that is, drugs designed for maintenance of the euthymic (normal) state while preventing the appearance of both manic and depressed episodes – are available. The first mood stabilizer to be used was lithium. Other commonly used mood stabilizers are valproic acid and its derivatives, and carbamazepine. The anticonvulsant lamotrigine has an established place in prophylaxis for bipolar depression. Antidepressants are generally not favored as prophylaxis in people with bipolar disorder, as they can make mood unstable: certainly they should not be used in the absence of a mood stabilizer. The atypical antipsychotics (see Section Schizophrenia) are increasingly used for people with bipolar disorder, both in acute phase as well as maintenance (Malhi et al., 2010).

Lithium bears particular attention as it was the first mood stabilizer, and is arguably still the 'gold standard' treatment. Three early open trials suggested that lithium may be effective in the prophylaxis of bipolar disorders (Baastrup, 1964; Hartigan, 1963; Baastrup and Schou, 1967). During the 1970s, a series of double blind studies were conducted to examine the possible efficacy of lithium in the prophylaxis of bipolar disorder. Goodwin (1994) summarized these studies calculating the recurrence rates over a 1-year period for placebo (a nonactive treatment) to be 81%, but only 34% for lithium. These reports included two types of studies: prospective studies treating patients with either lithium or placebo; and discontinuation studies where one group of patients continues with lithium treatment for a given period of time, whereas the other discontinues treatment for a similar time period.

From the 1980s and on, more prospective and discontinuation studies were conducted. These studies basically confirmed lithium's efficacy as maintenance treatment for bipolar disorder. They also suggested that there may be an advantage in keeping maintenance lithium blood levels at about 0.6 meq/l, as it may be associated with fewer side effects and improved adherence (Coppen et al., 1983), and that lithium plasma levels of 0.8–1.0 meq/l seem to be associated with lower rates of relapse (Gelenberg et al., 1989). In general, although many authors still suggest that lithium is an efficient drug for bipolar illness, especially in the classic bipolar patient (Grof, 1999), some experts now point to the fact that there is a group of patients who are less responsive to this drug or that demonstrate a decreased response throughout the years. There is also the problem of potential renal dysfunction in conjunction with lithium use.

One important issue associated with long-term maintenance therapy is the finding of predictors for a beneficial, or lack of, response for a given drug. Several predictors of lithium response were offered. Grof et al. (1983a,b, 1999) suggested a better response to lithium treatment in a group of patients demonstrating a course of illness with periods of euthymia (normal range of mood), followed by mania, depression, and then again euthymia. These authors also suggested that the absence of rapid cycling (four and more illness episodes per year), the absence of personality disorder, and the diagnosis of primary bipolar disorder (i.e., not secondary to street drugs or organic cause) predict a good prophylactic response to lithium. Faedda et al. (1991) in agreement with Grof suggested that mania–depression–euthymia course is associated with a good response to lithium. Others suggested that good response to lithium in relatives and a family history of mood disorders carry a good response. Aagaard and Vestegaard (1990) suggested that bipolar patients tend to demonstrate decreased response to lithium treatment when they have a lengthy episode, they are young or of female gender. Abou-Saleh and Coppen (1990) suggested that positive prophylactic response to lithium over 6–12 months predicts further good response in the future. Patients with dysphoria and mixed mania (manic episode associated with some depressive symptomatology) were suggested to respond less to lithium treatment, and some studies suggest this is also true for rapid cycling bipolar disorder. Hopefully, a knowledgeable use of predictors may help the physician to choose selected subgroups of patients, who will benefit from lithium maintenance treatment and who will require other medications or combinations thereof. For a recent pragmatic review of the pharmacological treatment of bipolar disorder, the reader is directed to Malhi et al. (2010).

Again, it is important to appreciate that even with excellent medication adherence, people with bipolar disorder remain very vulnerable to the recurrence of both manic and depressive episodes. There is increasing excellent evidence to support the adjunctive use of targeted psychosocial interventions as prophylaxis. Strategies include psychoeducation, mood monitoring, mapping early warning signs, cognitive behavior therapy, and interpersonal and social rhythm therapy. The interested reader is referred to the clinical review by Lauder et al. (2010).

Maintenance Treatment in Major Depression

Depression is a serious illness, with substantial suffering and disability and a high suicide risk. Recurrence rates in people with major depression have been estimated to be as high as 80%. Two types of studies report the efficacy of antidepressants to prevent relapse in the first year after remission from a depressive episode. The first is a crossover design, while the second employs a continuation design. In the first type of study, patients are first brought into remission with a given medication and are then maintained on that medication for a period of 2–3 months. Patients who respond are then entered into a double blind phase for up to another year, in which they receive randomly either the same antidepressant or placebo. In the continuation design, acutely depressed patients are assigned randomly to either active drug or placebo. Patients who respond continue with the same treatment. Eighteen studies compared a group of antidepressants collectively called tertiary amine tricyclics (this name describes the common molecular structure characterizing this group of drugs) finding that while 50% relapsed on placebo, only 23% relapsed on the active drugs. Three studies compared another group of newer antidepressants collectively called selective serotonin reuptake inhibitors (this name describes the hypothesized mechanism of action of this group of drugs) finding that the relapse rate for the active drug was 13–26% whereas for placebo it was 46–57% (see Janicak et al., 1997). More recent studies have shown prophylactic efficacy for the newer antidepressants, including the serotonin–noradrenaline reuptake inhibitors, the presynaptic anticholinergic receptor antagonist mirtazapine, and the melatonin M1 receptor agonist agomelatine.

In general, it is agreed that prevention of relapse in major depressive illness is of major importance and every effort must be taken to address this. Contrary to the early reports that supported the use of low doses of medication in the prophylactic treatment of major depression, several authors now recommend the use of full dose; that is, a similar dose to that used for the acute treatment of a major depressive episode.

In general, it is recommended to continue maintenance treatment after a first episode of major depression for about 6 months and then to taper the drug gradually. If another episode occurs, the recommendation is to continue treatment for several years, and after a third episode lifetime maintenance treatment is recommended.

Physical Health Prophylaxis in Psychiatry

It is increasingly recognized that people with mental illnesses often suffer an undue burden of underrecognized and undertreated physical morbidities. In people with schizophrenia, for example, life expectancy is some 15–20 years lower than that of the general population. Most of this excess in early death is due to cardiovascular illness. In a recent national survey of people with psychotic disorders conducted across seven sites in Australia, around a quarter of respondents were considered at high cardiovascular disease risk, with high rates of undertreatment (Galletly et al., 2012).

These distressing statistics are compounded by the fact that a number of the medications used to manage the symptoms of mental illness over protracted periods cause or exacerbate risk factors such as obesity, diabetes, and hypercholesterolemia. A number of the atypical antipsychotics are particularly implicated in this regard, but valproic acid and lithium also carry the risk of weight gain and other medical problems.

In considering prophylaxis in psychiatry, then, it is imperative to ensure adequate psychoeducation as well as effective monitoring and targeted interventions for physical health problems. Various strategies have been looked at in this regard, with the most successful being where physical health is imbedded into mainstream mental health services (e.g., Organ et al., 2010), with agreed care pathways and referral networks to other health professionals (including dieticians, exercise physiologists, and medical specialists such as endocrinologists, as required). Primary care providers can play a key role in optimizing the physical health of the mentally ill.

Adherence and Its Importance in Prophylaxis in Psychiatry

Adherence to drug treatment is defined as adherence to an agreed treatment schedule between a physician and a patient. It is estimated that not more than 50% of patients fully adhere to their treatment and it is suspected that the magnitude of non-adherence may be even greater in the case of long-term maintenance treatment. Various factors influence adherence, including the nature of the patient–physician relationship, the patient's set of beliefs and expectations, as well as the occurrence of side effects. Issues of particular relevance to adherence in psychiatric disorders are (1) the occurrence of delusions and severe cognitive distortions about the index drug and its effects and side effects; (2) the patient's cognitive functioning and motivation, which may be impaired in certain psychiatric disorders; and (3) the patient's general attitude toward mental illness. Especially important in this context is the level of stigma felt by the patient: the greater the stigma, the less adherent the patient is likely to be.

Several strategies can be offered to enhance adherence and these should be tailored according to the patient's condition and level of understanding. First, an empathic approach, one that builds basic trust with the patient and their family is of utmost importance. Second, whenever possible, the patient with the guidance of their physician should be an active participant in decisions made for the treatment plan. This does not mean that the patient decides or dictates such decision making, but that they are presented with several treatment alternatives and an educated decision is agreed upon with the guidance of the physician. Third, the patient should be educated as to side effects and ways to cope with those once they appear. Treatment diaries and involvement of family members whenever necessary can also be of help. Since maintenance treatment is long term, it is our opinion that a responsible physician should renew such a drug treatment 'agreement' at least every several months, discussing it with the patient, and perhaps with relevant family and community members if needed. The physician should also actively ask in each meeting with the patient about side effects as well as examine whether there is any change in the patient's set of beliefs about the drug and its action that may need renewed education.

Future Directions for Prophylaxis in Psychiatry

Genetic epidemiological studies have shown that genes play a major role in several psychiatric disorders including schizophrenia, bipolar illness, and major depression. It is now believed that these disorders are not related to a single gene, but rather are determined polygenetically. In general, it seems that gene–environment interactions are involved in the causation of many psychiatric disorders. Interestingly, the vulnerability to environmental influences may also be genetically determined (see Owen et al., 2000, for review).

The human genome project, now completed, is expected to contribute to the finding of genes responsible for the susceptibility, occurrence, and maintenance of these disorders. The sorting out of genetic variations in the population, which are related to these psychiatric disorders, may open new avenues to genetic medical interventions prior to the manifestation of these diseases. Such interventions may alter the course or even prevent these diseases from occurring. Although this project is still far off, one cannot ignore it at the dawn of this new era, which started with the recent completion of the decoding of the human genome.

Proportional Representation

Jack H Nagel, University of Pennsylvania, Philadelphia, PA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Proportional representation (PR) refers to electoral systems designed to approximate the ideal of proportionality in converting citizens' votes into legislative seats. All PR systems require multimember constituencies. In the most common form, list PR, electors vote for lists of candidates designated by parties. In a hybrid variant, mixed-member proportional, about half the representatives are elected from single-member districts and half from party lists, but seats won in districts are subtracted from list allocations so they do not diminish overall proportionality. The least common version of PR, the single-transferable vote, permits voters to rank individual candidates, crossing party lines if they wish. The degree to which a PR scheme approaches proportionality depends on the number of representatives elected per constituency, the formula used to convert votes into seats, the compensatory use of higher tiers of representation above the basic constituencies, and the application of vote thresholds for representation. PR methods were first adopted for national elections by Belgium in 1899. They are now employed in many countries around the world and are dominant in Europe and Latin America.

As a standard for making political evaluations, 'proportional representation' (PR) implies that representatives of a group (R_g) participate in a legislature or other governmental entity in numbers that bear the same ratio to the total membership of that body (R) as persons belonging to or identifying with the group (P_g) have to the total population governed (P) – thus, $R_g/R = P_g/P$. The groups in question may be residents of territorial subdivisions; persons sharing identities based on race, ethnicity, religion, language, or gender; or adherents of ideological or policy tendencies; but most often the relevant groups are political parties. 'PR' also, and more commonly, refers to methods of electing representatives designed to achieve an approximation to that standard in converting citizens' votes into seats in a legislature or council. In this article, 'PR' will indicate such electoral systems, while the ideal at which they aim will be referred to as 'proportionality.'

Although the concept of proportionality is simple, PR electoral systems are highly diverse, varying with choices made from a menu of design elements, some of which are complex and nonobvious. One feature that all PR systems require is the use of multimember districts – constituencies from which more than one representative is to be chosen. Therefore, except in the limiting sense that the winner should have more votes than any loser, PR does not apply to elections that choose a single winner, such as contests for executive posts (e.g., a president, governor, or mayor) or for legislative seats from single-member districts (SMDs). In the study of legislatures, a bifurcation is thus often made between PR and SMD systems, the former sometimes called 'proportional' and the latter 'majoritarian,' although design choices within those two broad families affect the degree to which either label is actually appropriate.

Three Types of PR Electoral Systems

Despite great and often idiosyncratic variation, PR electoral systems can be divided into three broad types, of which the first is by far the most common.

List PR

In the pure form of list PR, the 'closed list,' political parties designate before the election a rank-ordered list of candidates. Electors vote for a party, not for individual nominees. Each party wins seats proportional to the votes cast for its list. For example, if 10 representatives are to be elected from a constituency, a party winning 20% of the vote should be awarded two seats; these will go the candidates ranked first and second on the party's list. List PR systems are employed for national parliamentary elections in most countries of continental Europe and Latin America, as well as some countries in other regions.

The Single-Transferable Vote

Single-transferable vote (STV), also known as the quota-preferential system, depends on a preferential ballot, which asks voters to rank individual candidates (not parties) from most to least preferred. A quota of votes, Q, is established. All candidates receiving Q or more first preferences are elected. To determine the remaining winners, two types of transfers are carried out. First, 'surplus' votes (those above Q) received by winning candidates are 'transferred' to voters' second (or, if necessary, subsequent) choices. If seats remain unfilled after all surplus votes have been reassigned, then the candidate ranking last in votes is eliminated, and ballots giving first preferences to him or her are transferred to the voters' second (or subsequent) choices. These transfers are iterated until quotas are attained by the required number of candidates. Perhaps because of its complexity, both in balloting and in the procedure for selecting winners, STV is employed in national elections by just a few countries – Ireland, Malta, and (for the Senate only) Australia.

Mixed-Member Proportional

In an effort to combine the virtues of proportionality and local representation, West Germany after World War II pioneered the hybrid 'mixed-member proportional' (MMP) system. In MMP, some representatives (half in Germany) are elected

from single-member districts, and the rest are elected from party lists. Electors cast two votes – one for an individual constituency representative and one for a party. Seats that parties win from constituencies are subtracted from their list allocations to make overall delegations proportional to party votes. This crucial 'compensatory' feature makes MMP a truly proportional system.

Semiproportional Systems

Several systems that may be described as 'semiproportional' are intended to offer some representation to minority parties or groups, but offer less likelihood of approaching true proportionality, compared with the three main types of PR.

Parallel Systems

A second mixed type, easily confused with MMP, is the 'parallel' system (also known as mixed-member parallel and mixed-member majoritarian). Like MMP, parallel systems elect some legislators from single-member constituencies and some from PR lists. Parallel systems diverge from MMP by not compensating for constituency victories in allocating seats to party lists. In effect, the legislature is chosen by an amalgamation of two separate electoral systems, only one of which aims at proportionality. If, as is usually the case, seats chosen by PR comprise no more than half the assembly, then the parallel system is appropriately classified as semiproportional. Japan and Russia both adopted parallel systems in 1993, but Russia switched to list PR beginning with its 2007 election.

Limited and Cumulative Voting

The term 'semiproportional' is also applied to electoral systems that are intended to achieve a degree of proportionality, but do not employ PR formulas to do so. These systems use multimember districts, voting for individual candidates, and the plurality formula. The opportunity for more proportional outcomes arises from their unusual balloting rules. The 'limited vote' requires electors to cast fewer votes than the number of representatives to be elected (M). In the extreme version, known as the 'single-nontransferable vote' (SNTV), electors may vote for only one candidate, even though $M > 1$ will be elected. Japan employed SNTV until 1993, and Afghanistan adopted SNTV early in the twenty-first century for elections to the House of the People. 'Cumulative' voting gives electors M votes but allows them to 'cumulate' votes, by casting more than one of the votes for a favored candidate or candidates. Cumulative voting is not used for any national legislature, but it is employed in some U.S. local elections. Limited voting and cumulative voting, which have similar underlying strategic properties, enable well-coordinated minorities to win seats. However, because parties must avoid dispersing votes among too many candidates, these systems tend to reduce competition, and such competition as does occur tends to be within parties or voting blocs, causing internal conflict and factionalism.

Design Elements of PR Systems

In establishing any system of PR, choices must be made about various essential elements. These decisions affect the degree of proportionality that elections can deliver, the ability of smaller parties to win representation, and other aspects of how the system will function in practice.

District Magnitude

The degree to which a PR electoral scheme can approach perfect proportionality depends most strongly on the number of representatives elected per constituency, or 'district magnitude' (M). For example, if Parties A, B, and C receive 50, 40, and 10% of the vote respectively, and $M = 2$, then most PR formulas will give A and B one seat each, while shutting out C entirely – a very crude approximation to proportionality. In contrast, if $M = 100$, A can receive 50 seats, B 40, and C 10, resulting in perfect proportionality. The greatest magnitudes occur when the entire nation constitutes a single constituency, as in Israel and the Netherlands, where M equals 120 and 150, respectively. In most PR systems, however, the country is divided into multiple constituencies with lesser magnitudes, to ensure representation for different geographic areas.

Formulas

Although perfect proportionality is easy to achieve in contrived examples like the one above, in real elections the numbers seldom work out so evenly. For example, if $M = 10$ and Party C wins 15% of the vote, should it receive one or two representatives? To solve such problems, PR systems in practice employ mathematical formulas or algorithms that allocate seats to lists. These formulas employ one of two basic mechanisms – divisors or quotas. In divisor (or highest average) methods, seats are assigned sequentially. Each seat goes to the party which, at that point in the allocation, has the largest quotient after its votes are divided by a divisor (D) that varies with the number of seats the party has already received (S). Well-known divisors include the D'Hondt formula, $D = S + 1$, thus producing the sequence of divisors 1, 2, 3, …; and the Sainte-Laguë formula, $D = 2S + 1$, resulting in the sequence 1, 3, 5, …. In quota (or largest remainder) formulas, parties receive an initial allocation of seats equal to the number of quotas achieved in the vote for their list. The quota (Q) is determined by dividing total votes by M (Hare or natural quota), $M + 1$ (Droop quota), or $M + 2$ (Imperiale quota). Any remaining seats are assigned according to largest remainders – that is, by the size of parties' leftover votes after subtracting the quotas they have already used. Quotas are also employed to award seats in STV.

Over the years, PR formulas have inspired much political controversy, because different divisors and quotas favor large, medium, or small parties – for example, D'Hondt tends to give more seats to larger parties, whereas Sainte-Laguë approximates proportionality more closely, thus benefiting smaller parties. Nevertheless, district magnitude has a far more powerful effect on parties' fortunes; small parties generally do better as M rises.

Besides their use to determine the winners of legislative elections, PR formulas have two other important applications.

They can be used for 'apportionment' – the assignment of seats to districts (e.g., states) in proportion to population, as is required for the U.S. House of Representatives following each decennial census. In fact, several of the major PR formulas were first devised by American statesmen (Jefferson, Hamilton, and Webster) to apportion House seats prior to their later, independent invention in Europe to allocate seats based on electoral results (Balinski and Young, 2001). More recently, the D'Hondt divisor rule has been employed to structure the sequential allocation of cabinet portfolios to parties in Northern Ireland as a crucial part of the 1998 Good Friday peace accords. Similar procedures are used to assign executive responsibilities to council members in some Danish municipalities and for choosing committee chairs in the European Parliament (O'Leary et al., 2005).

Tiers

The use of relatively low-magnitude constituencies offers better geographic representation but may result in considerable departures from proportionality when votes and seats are compared nationwide. As a corrective, some PR systems include a second, national 'tier' of representatives (sometimes called 'additional' or 'supplementary' members) who are selected in a compensatory fashion. That is, parties that are underrepresented after assignment of constituency seats receive more of the second-tier seats, so as to establish a closer approximation to proportionality across the country as a whole. Except for Finland, all the Scandinavian countries use a second tier of seats for this purpose. The concept is similar to MMP, except that tiered PR systems generally ask citizens to cast only one vote, not two as in MMP; and MMP does not attempt proportionality at the constituency level. As a result, compared with two-tier list PR, MMP systems require a higher percentage of compensatory seats to achieve reasonable overall proportionality.

An implicit second tier is also involved in a novel proposal that, at first glance, appears to defy the usual axiom that PR requires multimember constituencies. That is the plan for 'fair majority voting' devised by Balinski (2008) as a way to neutralize partisan gerrymandering in the United States, where a federal statute mandates that all states use single-member districts for elections to the House of Representatives. Under Balinski's plan, elections would be conducted in each district, just as they are under the current system. However, votes for district candidates would also be tallied at the state level and credited to the candidates' parties. If necessary to achieve greater proportionality statewide, certain plurality winners at the district level might be denied seats, which would be assigned instead to trailing candidates whose parties' allocations would otherwise be less than proportionate. Thus the state serves as a *de facto* second tier, but the lack of supplementary members at the state level necessitates the counterintuitive step of giving seats to district losers.

Thresholds

PR systems with high-magnitude districts, nationwide lists, or compensatory upper tiers can enable numerous small parties to win parliamentary seats. Critics of such 'permissive' PR systems condemn proliferation of small parties, contending that it confuses voters, complicates coalition formation, renders governments less stable, and obscures accountability for governmental performance. Perhaps the most influential objection is that lack of barriers to entry can award legislative seats to extremist, antidemocratic parties. Thus Hermens (1941) maintained that Weimar Germany's excessively permissive version of PR enabled the Nazi Party to gain a foothold in the Reichstag, which they exploited to establish a totalitarian regime. When democracy was restored in West Germany after World War II, the new MMP system included a requirement that a party must win at least 5% of the party vote to seat candidates from its party list. Such formal 'thresholds' are now common in list PR and MMP systems; they range from 0.67% in the Netherlands to 10% in Turkey. Low-magnitude systems, including STV, have no need of a formal threshold, because any PR formula applied to a small M imposes a high *de facto* threshold. The MMP systems of Germany and New Zealand also include an alternative threshold – parties can win list seats either by attaining the threshold percentage of the party vote or by winning a specified number of constituency seats (three in Germany and one in New Zealand). In New Zealand, this 'back-door' threshold has frequently enabled very small parties to receive list seats (Nagel, 2012).

When small parties or voters have not fully adapted to thresholds – the former by amalgamating and the latter by refraining from voting for parties likely to fall short of the requirement – then the imposition of a threshold can result in many 'wasted votes' and substantial departures from proportionality in an ostensibly PR system. Such outcomes are more likely during the early stages of democracy, as in several East European countries during the 1990s (Birch, 2003).

Choices in Balloting

PR systems also differ in the choices they allow voters to make as they cast ballots. 'Closed-list' PR requires voters to designate only their preferred party – effectively, a vote for its entire list in the preference order established by the party. In contrast, 'open-list' PR systems permit (or sometimes require, as in Brazil and Finland) voters to indicate preferences for individual candidates on their chosen party's list. In the 'panachage' system of Switzerland and Luxembourg, electors may even distribute votes for candidates across different party lists. In the STV version of PR, votes are cast for individuals, and electors may move back and forth across parties while ranking candidates. Closed-list PR assigns control over the fate of individual candidates to parties' internal decision processes (which determine their position on the list and thus their prospects for election), whereas STV reserves that power for voters, and open-list PR occupies an intermediate position. Consequently, closed-list PR strengthens party organization and promotes party discipline in the legislature, whereas STV and (usually to a lesser degree) open-list PR are conducive to intraparty electoral competition and individualistic behavior among legislators.

In practice, however, these differences may be blurred. In STV systems, unless district magnitude is kept low (on the order of three to five representatives per constituency), the task of ranking numerous candidates becomes so difficult that most voters will follow instructions given by their parties. That is the case in STV elections for the Australian Senate, where M equals 6 or sometimes 12, and voters must submit a complete ranking

of all candidates, who frequently total 30 or more. Thus, if it imposes excessive cognitive demands, a system intended to maximize the autonomous power of individual voters may end up functioning rather like closed-list PR.

Historical Development

Because PR methods are nonobvious and complex, their development stands as one of the key intellectual achievements in the history of democracy. The Marquis de Mirabeau enunciated the principle of proportionality in 1789, but methods designed to achieve it were not refined until well into the nineteenth century. In 1834 Victor Considérant devised a list PR system that Antoine Morin of Switzerland developed further in 1862. In 1885 an international conference on PR in Antwerp recommended the list PR method proposed a few years earlier by a Belgian, Victor D'Hondt. In 1899, Belgium adopted D'Hondt's system and thus became the first country to use list PR. By 1920 most countries of western Europe had adopted versions of PR (Carstairs, 1980).

Beside the intellectual and moral appeal of proportionality, two practical motives spurred the turn to PR in Europe. In societies divided along linguistic or religious lines, such as Switzerland, Belgium, and the Netherlands, PR offered all groups a stake in democracy. For countries about to expand the franchise, PR assured ruling groups and conservative parties that they would not be shut out of parliament, as might have occurred under existing plurality and majority electoral systems once previously disenfranchised citizens became a majority of voters. These motives also influenced later decisions to adopt PR, including the notable cases of South Africa in 1994 and Iraq in 2005.

Perhaps because of their long history of elections predating the development of PR, the United Kingdom and the United States (as well as some countries they influenced, including India and Canada) have clung to the older, simpler method of single-member districts and plurality rule (also known as 'first-past-the-post'). Reformers who promote PR in English-speaking countries have usually favored STV, reflecting its invention by the Englishman Thomas Hare in 1857 and John Stuart Mill's enthusiastic advocacy. That tradition was broken in 1993 when New Zealand replaced first-past-the-post with MMP. Subsequently, MMP was adopted for the new national assemblies in Scotland and Wales; but efforts in the early twenty-first century to establish MMP in the Canadian provinces of British Columbia, Québec, and Ontario fell short of approval. The major gain for PR in that period was Russia's switch from a parallel system to list PR.

Agreement on a list PR system was often a key ingredient in democratizations during the late twentieth century, as in Portugal, Spain, South Africa, and Indonesia. However, in the 1990s the global trend shifted to mixed electoral systems, both the semiproportional parallel version and fully proportional MMP. By 2013, of the world's 213 countries and territories with direct elections to the national legislature, 92 (43.2%) used PR systems (81 list PR, 8 MMP, and 2 STV) to elect the principal chamber. Another 25 countries used semiproportional systems (23 parallel and 2 SNTV) (International IDEA). In many nations, PR methods are also used for elections to upper chambers, regional and local councils, or supranational authorities, such as the European Parliament. However, on a population basis, SMD plurality (first-past-the-post) remains the most widely used method for electing national legislatures, mainly because it continues to be employed by the two most populous democracies, India and the United States (Reynolds et al., 2005: pp. 29–33).

Effects and Evaluations

The obvious intended benefit of PR systems is to establish what advocates consider an essential condition of electoral fairness – a close correspondence between parties' votes and seats. The use of a PR formula does not preclude significant deviations from proportionality when thresholds are high or district magnitudes are low, especially if parties have not yet adapted strategically to the parameters of the electoral system. However, PR systems as a group do succeed in delivering substantially more proportional outcomes than their chief rivals.

Although the immediate effect of list PR and MMP is to promote proportionality for political parties rather than underlying population groups, most parties will compete for votes of minority groups by placing members in electable list positions. If they do not, groups large enough to surpass the threshold can win representation by organizing their own parties. Consequently, these two versions of PR usually deliver improved representation to minorities. The same incentives apply to electing women. Where they have become politically active and organized, women generally win more legislative seats under list PR and MMP than under SMD systems; there is less evidence about whether STV helps women.

Because PR is less likely than SMD systems to waste votes cast for smaller parties, it usually results in multiparty parliaments. The association between PR and multipartyism must be regarded as permissive rather than automatic. Within the constraints imposed by the electoral framework (district magnitude, formula, tiers, and threshold), the number of parties depends on the number of societal cleavages and on the willingness and ability of politicians to exploit them by organizing parties. Proportionality and multipartyism together make one-party majorities rare, so parliaments elected by PR typically form coalition governments or minority governments that must get support from other parties to pass legislation. Again, the contrast with SMD systems is not absolute, because such outcomes are not uncommon under first-past-the-post, especially where smaller parties win seats from regional strongholds, as in Canada and India.

Critics of PR usually concede its representational advantages, but they contend that it produces a fragmented party system, unstable coalition governments, and excessive influence by extremist parties. Their favorite negative examples include Italy (before 1993 reforms), Israel, and Weimar Germany. In response, some advocates of PR recommend 'moderate PR' with districts of intermediate magnitude or (equivalently) significant thresholds, rather than the permissive forms those three cases exemplify. For example, Carey and Hix (2011) propose that 'effective magnitudes' (incorporating the effect of thresholds) between 4 and 8 offer a 'sweet spot,' because they deliver almost as much proportionality as higher magnitude systems while producing less fragmented party systems and simpler

governments. In contrast, McGann (2013) argues that low barriers to entry by new parties help protect against corruption and complacency among established parties.

Scholars' empirical evaluations of electoral systems tend to group them into two large families, 'proportional' and 'majoritarian.' Following the influential work of Lijphart (2012), the former is often identified with 'consensus' politics. PR is indeed an essential component – along with super-majoritarian decision rules, federalism, bicameralism, and other checks on majority rule – of the 'consociational democracy' model that Lijphart, O'Leary, and others prescribe for deeply divided societies. However, some of the most successful countries using PR are unicameral parliamentary systems that make legislative decisions by majority rule. These systems require frequent interparty negotiation to form majorities, but such agreements often fall far short of consensus. Moreover, evidence shows that countries within the so-called 'majoritarian' camp – especially those that actually decide elections by plurality rather than majority rule – less consistently form governments based on a majority of voters than do PR systems (Powell, 2000; McDonald and Budge, 2005). For these and other reasons, some scholars (e.g., Nagel, 2000; McGann, 2006) believe that PR elections to a majority-rule legislature provide the best guarantee of majoritarian outcomes.

A recent statistical literature attempts to link economic outcomes to electoral systems. Some of these studies have associated PR with greater income equality, more spending on welfare and pensions, higher governmental spending overall, larger deficits, and higher inflation (Persson and Tabellini, 2004; Rogowski and Kayser, 2002). However, such analyses usually rely on the crude dichotomy between proportional and majoritarian electoral systems, thus not taking into account the considerable variation within each family. Moreover, investigations that are confined to advanced economies (e.g., OECD members) have trouble separating the effect of electoral systems from the cultural, historical, and ideological gulf between Anglo-American and continental European democracies. Research with more extensive data bases includes many countries in Latin America, Africa, and Eastern Europe that have PR legislatures and strong directly elected presidents, a combination that some leading political scientists do not recommend (e.g., Lijphart, 1991).

Although long-standing controversies over the merits of PR continue, evidence suggests that most experts on electoral systems have high regard for PR. Of the nine alternatives presented to 170 experts in a survey, PR variants won four of the top five places. MMP finished a strong first, with 52 first preferences, followed by STV and open-list PR. Closed-list PR was edged out for fourth place by the alternative vote, an SMD system that uses majority rather than plurality rule. SMD plurality, the traditional rival to PR, finished a poor sixth in the evaluation, with only 21 of the 170 experts considering it the best. Overall, nearly 70% of the experts ranked one or another of the PR systems as their most preferred choice (Bowler et al., 2005).

Abstract

Prosecutors have been called the 'gatekeepers of criminal justice' because without their actions, judicial intervention and sanctions could not occur. However, a study of prosecution should not be limited to assessments of the prosecutor's role in individual cases. One must instead consider the ways in which countries deal with competing needs and limited resources when they establish and operate their prosecution systems. Because prosecution contributes substantially to the definition and implementation of criminal justice policy, any comprehensive examination of prosecutors' functions must include an analysis of their relationship to the state.

This article considers six of the most salient features of prosecution systems: (1) the degree to which prosecution is handled by public officials or private parties; (2) the degree to which the prosecutor's office is centralized or decentralized; (3) the independence and political accountability of the prosecutor; (4) the prosecutor's relationship to and with the police; (5) the prosecutor's discretion in charging; and (6) the prosecutor's role in court. The content of this article will be limited to the role of prosecution in democratic countries, but it ends with commentary about prosecution in a globalized criminal justice system that must deal with terrorism and war crimes in nations across the globe.

In its broadest sense, 'prosecution' signifies an aggrieved party's initiation and pursuit of a legal case through the court system. It begins with the filing of a complaint and continues through trial, awarding of remedies, and appeal. While this term technically applies to both civil and criminal matters, it is most commonly used in the criminal law context. In a criminal case, the term 'prosecution' refers to pursuing a criminal complaint against someone accused of a crime, usually by an official called a prosecutor, but occasionally by the complaining victim directly. This article focuses on the most common form of prosecution, a case brought by a public official against one charged with a crime. The authors draw on comparative studies to illuminate differences and similarities among prosecution systems throughout the world.

Prosecutors have been called the 'gatekeepers of criminal justice' because without their actions, judicial intervention and sanctions could not occur (Di Federico, 1998). However, a study of prosecution should not be limited to assessments of the prosecutor's role in individual cases. One must instead consider the ways in which countries deal with competing needs and limited resources when they establish and operate their prosecution systems. Because prosecution contributes substantially to the definition and implementation of criminal policy, any comprehensive examination of prosecutors' functions must include an analysis of their relationship to the state.

This article considers six of the most salient features of prosecution systems: (1) the degree to which prosecution is handled by public officials or private parties; (2) the degree to which the prosecutor's office is centralized or decentralized; (3) the independence and political accountability of the prosecutor; (4) the prosecutor's relationship to and with the police; (5) the prosecutor's discretion in charging; and (6) the prosecutor's role in court. The content of this article will be limited to the role of prosecution in democratic countries; for a discussion of criminal courts in nondemocratic nations (*see* Trials; Nazi Law; Socialist Law; Political Trials; War Crimes Tribunals, Crimes against Humanity and Transitional Justice; Law and Courts in Authoritarian States).

Public or Private Prosecution

In many legal systems, criminal law was once a branch of what scholars now call 'torts' (*see* Torts in Law), whose prosecution was initiated and pursued by the injured parties. With the rise of the modern state, crime became a distinct offense against the state itself, and responsibility for prosecution was assumed by the state (Langbein, 1974). This trend emerged earlier and more sharply in Europe than in England, where the system of privately initiated and financed prosecution remained in place well into the nineteenth century.

Prosecutors as Public Officials

In Europe and indeed in most places in the world, public prosecutors play a much larger role in the criminal process than they do in the United States and England. Continental prosecutors control the investigation of crime, often having direct supervisory powers over the police, and typically oversee the execution and disposition of almost all criminal arrests. This tradition derives largely from the institution of the *Ministère Publique* from the Napoleonic Code. Furthermore, some civil law countries combine the role of prosecutor and judge, allowing officials to move back and forth between the two positions at different points in their careers and sometimes within the same case. A number of non-Western countries that have based their criminal justice systems on German or French models (such as Japan and Korea) also permit role flexibility to varying degrees (*see also* Trials; Judges; Criminal Procedure: Adversarial and Inquisitorial Legal Systems). Recent developments in France and Italy, however, suggest the use of more clearly defined boundaries between criminal justice system actors.

Common law countries reject this expansive conception of the prosecutor's office and formally prohibit any degree of fluidity in roles, regarding such interchangeability as in conflict with due process and separation of powers principles (*see also* Due Process in Law). In common law countries such as the

 http://dx.doi.org/10.1016/B978-0-08-097086-8.86099-7

United States, prosecutors unilaterally (with very few exceptions) make filing and case-processing decisions. The investigative work is typically left to the police, and judging is the domain of elected or appointed members of the judiciary. (Of course, in actual practice, the discretion with which each of these actors is vested allows some flexibility in task performance; *see also* Plea Bargaining: A Comparative Analysis and Policing for examples. Moreover, state trial court judges often begin their careers as state prosecutors.) In England and Wales, the Crown Prosecution Service (CPS), established in 1985, comprises exclusively professional prosecutors under the authority of a national Director of Public Prosecutions, but like their American counterparts, British prosecutors have no real supervisory authority over the local police.

Elements of Private Prosecution

Since the mid-nineteenth century, public prosecutors everywhere have become more powerful and independent. However, since the 1970s, with the growth of the victims' rights movement in many countries, legislatures have begun to provide victims with a greater voice in criminal proceedings. The degree of victim empowerment varies tremendously among countries. For example, Belgian law recognizes that certain crimes (e.g., defamation) require a formal complaint by the victim in order for the public prosecutor to initiate a criminal case. Even in that event, however, the public prosecutor is not obligated to file charges. In Germany, a victim may act as a private prosecutor if the public prosecutor does not file charges, or may join the public prosecution as a joint plaintiff and support the prosecutor's case. A French crime victim who feels ignored by the authorities may file a civil case based on the criminal behavior. This action automatically initiates a criminal case, thereby forcing an otherwise reluctant public prosecutor to become involved.

American crime victims generally have no formal right to participate directly in criminal cases. Nonetheless, victim willingness to give evidence may greatly influence the prosecutor's decision to proceed with a case. Cooperative victims are not a prerequisite to a successful prosecution, but prosecutors often make their decisions based on victim proclivities (Vera, 1981). While a lay person cannot control the criminal case, a victim of crime in the United States can file a civil lawsuit against the defendant based on the same conduct at issue in the criminal case; the remedies available through the lawsuit are limited to civil damages, however. Interestingly, the role of private interests in prosecution has made a comeback in the United States, as scholars have recently debated the legitimacy of allowing private victims to finance investigations or prosecutions that are conducted by public officials (Kennedy, 1997).

Centralized or Decentralized Office

Scholars distinguish between highly centralized systems that place prosecutors in a national civil service hierarchy controlled by a ministry of justice, and decentralized systems where prosecutors are selected locally. Overall, these structural and institutional features are likely to be closely related to and nested in larger structures of government and to make significant differences (Damaska, 1981). Needless to say, variations exist between these extremes, and even within each category, according to hiring practices and filing controls.

At one extreme is the American experience. The vast majority of criminal cases – both serious and minor – in the United States are filed and processed at the state level. However, 'state control' is something of a misnomer, because most American prosecutors are county officials who enforce state law. The chief prosecutor of each county (usually called the District Attorney) is locally elected, while the deputies or assistants may be either career civil servants or employees of a specific administration. State attorneys general have little control over their behavior or filing practices, handling mostly training and appeals (Flemming et al., 1992). Each county operates its own hiring system and typically recruits graduates from local law schools. There is little advance training for the job; on-the-job training occurs locally, within the office or in short courses run by the state or statewide prosecutors' association. As a result, each office sets its priorities according to the demands of its electorate and according to the interests of its leaders; this can produce great diversity in policies among prosecutors' offices, even within the same state (Utz, 1978; Di Federico, 2005; Levine and Wright, 2012; but see Levine, 2006 for an example of statewide convergence around a set of norms).

At the other end of the continuum lie countries like France and Japan, where the procuracy is tightly controlled and hierarchical. For example, at the apex of the Japanese system sits the Supreme Public Prosecutors Office, followed by 8 High Public Prosecutors Offices and then 50 District Public Prosecutors Offices, which in turn are overseen by the Supreme Court. At the base are 452 Local Public Prosecutors Offices. The local offices prosecute relatively minor cases, while the district offices handle all serious crimes. Moreover, Japanese prosecutors are an elite; they graduated from top law schools, passed a rigorous bar exam, and completed 2 years of training at the Supreme Court's Legal Training Institute. Because they are overseen by the Supreme Court, Japanese prosecutors have close association with judges; indeed, prosecutors and judges can and often do move between positions. Due to this hierarchical oversight, Japanese prosecutors value consistency and follow well-understood and consistent patterns of decision making (Johnson, 1998, 2002). A similar set of practices holds for France as well (Hodgson, 2005).

A high degree of centralization tends to limit the impact of public opinion on individual prosecutors, and on the national prosecutors' office as a whole. Prosecutors in more decentralized systems – and the United States is the extreme – have vastly more discretion but are (at least in theory) subject to shifts in public opinion owing to the election of the local district attorney (Wright, 2009). These differences are not ironclad; some modern prosecutors in Italy, Spain, France, Portugal, and elsewhere are sensitive to public opinion, and at times actively court the media in order to generate public interest and support for their cases (Di Federico, 2005). But even so, without an electoral process, they have less need than their American counterparts to be attuned to public opinion.

Lastly, prosecutors in civil law countries that subscribe to the centralized, professionalized model tend to view their positions as careers; in contrast, many American prosecutors work for a few years and then leave government for private practice. These patterns have their pros and cons. Frequent

turnover can hinder development of a sense of confidence, professionalism, and independence, but the hierarchical service system has been criticized for producing insular prosecutors – individuals and local offices who pursue their own agendas, often reflective of personal idiosyncrasies, or political or social biases (Di Federico, 1998). Political oversight may be the answer. Yet where political loyalties run deep and are reinforced by family and clan association, political oversight would invariably result in political agenda setting within prosecutors' offices and undermine the independence (Nelken, 2011). Such politicization is not hypothetical; it is pervasive in many of the new democracies in Latin America and Eastern Europe, where party, class, and group loyalties undermine the civil service and rule-of-law norms (Brinks, 2008).

Independence and Accountability to the Public

Because prosecutors exercise vast powers, one of the greatest challenges for institutional design and one of the central concerns of both normative and empirical scholarship on prosecutors is the degree to which they are both independent and accountable (Barkow, 2009). How does one prevent selective prosecution of one's political opponents and make sure that prosecutors do not run roughshod over others' rights? Prosecutors must be both independent and accountable, but from whom and to whom? And to what extent? Complete independence suggests no boundaries, the freedom to pick and choose as one likes. Substantial accountability may mean responsible oversight, but it can mean that one binds officials to external criteria of questionable merit.

One solution to this dilemma is to adopt a policy of full prosecution; every offense known to officials for which there is probable cause must be prosecuted to the full extent of the law (Davis, 1969). This is the doctrine found in many criminal codes, both in civil law and common law countries, and a standard response prosecutors give to those inquiring about how they exercise the powers. However, even the most ardent of civil law systems recognize that 'full prosecution' does not mean full; rather, it means that there is a systematic and well-developed policy with respect to bringing or declining to bring charges that is followed consistently (Nelken, 2011).

Still other institutional devices have been adopted to assure prosecutorial independence and accountability. Most common throughout the democratic world is the establishment of a centralized and professionalized prosecutorial system, complete with civil service protections, hierarchical control within the office, professional advancement, and oversight by ministries of justice. This may produce a strong prosecutors' office, as in several Northern European countries and Japan, instilling in prosecutors a high sense of duty and obligation to professional norms. In countries with traditions of a strong civil service, this model works well (Barkow, 2009; Johnson, 2002; Langbein and Weinreb, 1977).

Other countries face considerable challenges attempting to enforce this degree of control over prosecutorial decision making. Historically, the United States has had a weak tradition of civil service and its people have been leery of those exercising governmental power. Accordingly, in the early nineteenth century, the states adopted the practice of electing both judges and chief prosecutors at the local (county) level. With the experience of colonial judges and prosecutors appointed in London still in mind, the objective was not to 'politicize' these offices, but to try to assure that those who exercised these powers did not do the bidding of distant political authorities. It was a way of assuring both independence and accountability. Of course, the situation has changed considerably. Since the early 1900s if not before, research has consistently revealed that American prosecutors, both elected (state) and appointed (federal) are highly subject to political whim and consistently support 'get tough' policies (Wright, 2009). Furthermore, the office of chief prosecutor at both the local and the federal level is often a springboard for seeking electoral office, and given the near continuous 'war on crime,' this almost always means that prosecutors with an eye toward future electoral office are likely to support expanded criminalization, harsh sentencing laws, and vigorous prosecution. This connection exacerbates the politicization of crime, and by itself goes a long way to explaining why the United States is distinctive in the harshness of its justice (Stuntz, 2012; Davis, 2007; Flemming et al., 1992). In contrast, in Germany, Japan, the Scandinavian countries, and elsewhere, crime policy is viewed as a technical issue usually best left in the hands of the experts, which include prosecutors (Johnson, 2002; Weigand, 1999).

Relationship to and with Police

Is a prosecutor a justice official or a member of law enforcement? While Langbein (1974) reports that English justices of the peace served as both investigators and prosecutors in the fourteenth and fifteenth centuries, most countries today have formally separated the roles of police and prosecutor. Nonetheless, prosecutors vary in the degree to which they supervise or participate in police investigations. A prosecutor may bring a high level of control to police activities by formally supervising a police investigation (before or after bringing charges), by interviewing witnesses, or by attending the execution of search warrants. In contrast, a prosecutor may manifest low levels of control by simply filing charges in response to documents and evidence collected and submitted by investigating police officers.

In code-based countries with strongly centralized prosecution agencies, greater participation and supervision has long been the norm, at least in theory. Police in those nations may be statutorily required to notify prosecutors of an ongoing investigation or the detention of suspects, and the prosecutor can directly interrogate suspects or collect evidence. Systematic empirical literature on prosecutor–police relations is sparse, despite the lively debate over the degree to which prosecutorial oversight and investigative authority may serve as a useful check on police power. Some suggest it has substantial impact (Johnson, 2002; Frase, 1990, 1999), while others maintain that it is largely myth (Hodgson, 2005). Stefan Braum, for example, has argued that, although the European Court of Human Rights considers excessive police power to pose a risk to security and human rights, many European countries these days have public prosecution services that exert only weak control over the police. That is, with the integration of Europe into the

European Union and with the rise of terrorist activity in the twenty-first century, the international law enforcement agency Europol has grown in strength, subject to neither prosecutorial nor judicial control of any meaningful sort (Braum, 2012).

Low levels of prosecutorial control over police have long characterized common law countries like the United States; police typically handle the investigation and arrest phases of a criminal matter and notify the prosecutor only after arrest. While federal level prosecutors often become far more involved in the investigatory phases, coordinating wiretaps, search warrants, and witness interviews, most state prosecutors do not interrogate suspects or assist in the collection of evidence (Leo, 1996). Hence, police often control the flow of information on which prosecutors must rely in order to decide whether and what crimes to charge. This has led some commentators to conclude that prosecutors do little more than ratify police decisions (Feeley and Lazerson, 1983), rendering the arrest itself far more significant than the prosecutor's filing decision. The same tendency has been observed in Canada (Grosman, 1969).

The division of labor between police and prosecutors is not always clear-cut or unproblematic, as police behavior can influence both the onset and eventual disposition of a criminal case (Skolnick, 1975). These tensions are manifest in the British experience. The police were Britain's public prosecutors from 1829 to 1986, due to the absence of a suitable alternative; during this period, they developed a vested interest in controlling all stages of criminal cases – from investigation to arrest to prosecution (Fionda, 1995). The CPS was created to separate police and prosecutorial functions in order to remedy a perceived lack of police objectivity in prosecutorial duties, such as the filing and disposing of cases. However, in the years since the creation of the CPS, police officers have fought for control over filing decisions and have been accused of manipulating files and witnesses to influence prosecutors' options (Nduka-Eze, 1995). (*See* Crime Policy in the United States.)

Prosecutorial Discretion at Charging

Perhaps the central scholarly question about prosecutors is how they exercise their vast discretion to bring or decline a case, and if they opt for the former, what crime(s) to charge. Over the past 100 years in the United States and England, an extensive literature has addressed the issue of prosecutorial discretion and its implications for the just administration of the criminal law. Until the 1980s, scholarship on prosecutors in most civil law countries maintained that prosecutors exercise no or very little discretion since they operate under a system of full and mandatory prosecution; this claim at times has engendered a lively debate between those who maintained that even under compulsory prosecution schemes there is considerable discretion and plea bargaining (Goldstein and Marcus, 1977a,b) and those who believed there is not (Langbein and Weinreb, 1977). Whatever once may have been the case, scholars generally concede that at least since the 1980s, prosecutorial discretion in bringing charges and in negotiating charges and sentence recommendations has expanded tremendously (Luna and Wade, 2012).

Several factors account for this enlargement of the prosecutor's power in nations across the globe. First, more governments have sought to expedite court proceedings by relying more heavily on oral presentations and less on dossiers. Because prosecutors control the oral presentation of evidence and argument, the power over courtroom proceedings has shifted markedly from judges to prosecutors in jurisdictions following this trend (Caianiello, 2012; Kyprianou, 2009).

More importantly, however, we have seen the emergence of plea bargaining in countries that previously prohibited it (at least as an official matter) (Turner, 2009; Bradley, 2012) (*see also* Legal Issues: Public Opinion). While the reasons for adoption and forms of the practice vary, it seems to have taken hold across national borders. For example, some countries (like Italy) have introduced plea bargaining in order to secure finality of process; others, in their efforts to clamp down on drug conspiracies and organized crime, have embraced the time-honored Anglo-American practice of trading leniency for information implicating more important actors in criminal organizations (known as the little fish–big fish phenomenon). Still others have statutorily granted discounts to those who plead guilty (Caianiello, 2012). One can also find examples of countries, such as Russia and Bulgaria, adopting plea bargaining but imposing limits on how that practice is conducted, such as by prohibiting plea bargaining in serious violent crimes and prohibiting charge bargaining (Turner, 2009: p. 140). Notably, exceptions to these global trends can be found in Asia – while India began the practice in 2006 and Taiwan did so in 2004, China and Japan have so far refused to pursue plea bargaining as a formal policy (Turner, 2009: p. 171).

Political developments since the 1980s have expanded prosecutor discretion and hence power in plea negotiations. The near worldwide 'war on crime,' which began in the early 1980s, produced a 'culture of control' in many countries (Garland, 2001), a culture that is characterized at least in part by substantially harsher legislative sentencing ranges and public commitment to more vigorous prosecution. Harsher mandatory minimum sentences, three strikes or career criminal laws, sentence guidelines, and other legislative efforts to 'structure' sentences have resulted in more discretionary power for prosecutors, because they can circumvent legislatively 'mandated' draconian outcomes in exchange for pleas of guilty to offenses carrying lesser but still harsh penalties. Such developments have occurred worldwide, but the effects are most evident in the United States (Garland, 2001).

At the same time, legislatively created 'alternatives' to prosecution and supervised probation have expanded, and prosecutors have seized on these programs to gain still more discretionary power. Against the threat of substantial criminal charges, prosecutors can successfully press those charged with lesser offenses to agree to a variety of conditions for noncustodial supervision and surveillance, perhaps even reduced due process rights, in exchange for the government's agreement to drop or suspend prosecution (Wade, 2006). Moreover, those on probation who are arrested on new charges (often obtained because of probationers' diminished due process rights) are frequently offered a deal: waive the right to a probation revocation hearing and the new charges will be dropped. If accepted, the deal allows law enforcement to send a person back to prison

almost immediately and with only a peremptory appearance in court (Greenspan, 2014).

In hierarchically organized prosecution systems, one is likely to find national prosecutorial policies governing these exercises of discretion, but in decentralized systems, policies emanate from supervisors in individual offices, leading to troubling disparities across jurisdictions that are all subject to the same formal law. For example, in the United States, many states have statutes authorizing the death penalty for certain forms of murder, but the rate of filing capital charges for similar crimes varies tremendously among the individual counties (American Bar Association, 2006). Even with this variation in filing practice, prosecutors in all jurisdictions regularly rely on plea bargaining to secure guilty pleas in exchange for not filing capital charges (Thaxton, 2013). This is not just a capital murder phenomenon; what holds for these occasional high-stakes, high-visibility cases also holds for much more frequent 'ordinary' cases.

The power of the prosecutor is most evident in the declining rate of criminal trials. In the United States and England, for example, the rate of criminal trials, never high since the late nineteenth century, has plummeted to nearly zero (Galanter, 2004; Mulcahy, 2013; Wright, 2005). Indeed, since the 1990s, commentators have begun to describe the American criminal justice system as an administrative system driven by prosecutors rather than presided over by judges (Lynch, 1998), leading for calls to reform what they see as a dysfunctional and broken system of justice (Stuntz, 2012; Barkow, 2008). What holds most clearly in the United States is found elsewhere as well (Guarneri and Pederzolo, 2001).

Roles in Court

The final point of comparison concerns the prosecutor's role during the trial of a criminal case. The prosecutor's role will largely be determined by the type of trial system in which he or she works (adversarial, inquisitorial, or some mixture thereof; *see* Trials; Criminal Procedure: Adversarial and Inquisitorial Legal Systems). The prosecutor may be an active adversarial participant striving to win a conviction, or a more passive, impartial actor charged with ensuring that justice results.

When the trial depends largely on the contents of a written dossier (in countries such as Japan, Argentina, France, and Germany), the prosecutor is generally more passive; he or she submits the dossier containing the investigative reports to the judge (or to the panel of judges) before trial, but generally relinquishes control over questioning of witnesses. In many of these systems, the prosecutor is obligated to ask the judge for an acquittal following trial if the evidence merits this result, and the prosecutor typically has the right to appeal both the outcome of the case and the sentence.

In systems that require oral testimony (including Italy, Great Britain, Israel, and the United States), the prosecutor is the principal player in the courtroom. The prosecutor may sit near the fact finders or judges to establish rapport; controls the majority of the witnesses and the presentation of evidence; and argues the case both first and last, providing both the initial opening statement and the final closing argument. For this reason, prosecutors in oral-trial systems may feel more personally invested in the outcome of a case and often place tremendous pressure on themselves to win convictions (Heilbroner, 1990; Baker, 1999). In some countries, they have no right to appeal acquittals.

In the United States, where prosecutors are more autonomous than perhaps anywhere else in the world, some prosecutors have experimented with new roles, which Levine has labeled 'the new prosecution' and 'problem-solving prosecution' (Levine, 2005, 2007). Prosecutors have always exercised considerable discretion to drop and reduce charges, but she has found that some American prosecutors have experimented with community-based efforts to 'solve' problems that, while technically criminal, are better handled (they believe) with a social services approach – albeit with the threat of full prosecution in the background. Many such prosecutors have joined with judges and defense attorneys to develop problem-solving courts for arrestees with substance abuse problems, mental health problems, or domestic problems. Or on a more ad hoc basis, they may use the threat of prosecution to extract agreement from a father to provide financial support for his child or to seek treatment for alcoholism (Levine, 2005).

Conclusion: New Issues in the Twenty-First Century

Up until this point, the article has focused exclusively on prosecution policies and practices in domestic fora. But in the twenty-first century, as crimes against humanity increasingly seem to transcend national borders, prosecutors everywhere have had to deal with a globalized criminal justice system. This challenge is manifest in the International Criminal Court, with prosecutions of genocide and other war crimes, as well as in prosecutions of terrorist organizations in domestic and military tribunals (*see* War Crimes Tribunals, Crimes against Humanity and Transitional Justice; Law and Terrorism in the US and Beyond; Human Rights: Legal Aspects; Torture: Legal Perspectives; International Law and Treaties). Some commentators are even exploring the possible creation of a European Public Prosecutor's Office to handle transborder criminal disputes (Ligeti, 2013).

Even more so than their domestic law counterparts, prosecutors in globalized criminal justice systems have faced questions about the quality of evidence necessary to mount a successful prosecution, which investigative techniques are acceptable means to extract information, and the advisability of plea bargaining in these extremely serious crimes (particularly whether to give immunity to lower level players in order to obtain their testimony against the leaders of these organizations). Moreover, prosecutors handling terrorism and war crimes cases must keep in mind a range of goals. Beyond conviction of the guilty, identification of the innocent, deterrence of future wrongdoing, and provision of voice and closure to victims, globalized prosecutions of terrorists and war criminals can facilitate long-term peace in a troubled region and shed light on horrific events that might otherwise remain secret. Prosecutors cannot unilaterally achieve these aims, but their support for certain approaches (or, likewise, their resistance to certain approaches) can give preference to one set of goals over another. In essence, as Luna and Wade (2012) have observed, "(Like) their domestic colleagues, international prosecutors must become thoughtful policymakers and case managers in light of the lofty, if not unachievable, goals placed on imperfect systems of justice" (Luna and Wade, 2012: p. 287).

Prosocial Behavior and Empathy

John F Dovidio and Jillian C Banfield, Yale University, New Haven, CT, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Both cognitive empathy (perspective taking) and emotional empathy (affective reactions to another person's need) are critical determinants of adult prosocial behavior. Empathy can elicit altruistically motivated helping, reflecting desire primarily to improve another person's welfare. In general, people experience more empathy and exhibit greater prosocial behavior toward others who are in greater need, are more similar to the potential helper, and are members of the helper's social group. Evoking cognitive or emotional empathy toward a member of another group not only promotes prosocial behavior, but also improves attitudes toward the other group as a whole.

Prosocial Behavior and Empathy (in Adulthood)

Prosocial behavior represents a broad category of acts, such as helping, sharing, comforting, donating, or volunteering, and cooperation, that are intended to benefit others. Research on prosocial behavior has addressed not only the antecedents and consequences of these actions, but also the different motivations that may underlie these behaviors. Prosocial actions can be either altruistically or egoistically motivated (Batson, 2011). Altruistic motivation has the ultimate goal of increasing another person's welfare; egoistic motivation has the primary objective of improving one's own welfare. In addition, prosocial behaviors are shaped by both cognitive (e.g., assessments of costs and rewards) and affective (e.g., arousal and emotion) processes.

Empathy is a response that 'stems from another's emotional state or condition, is congruent with the other's emotional state or condition, and involves at least a minimal degree of differentiation between the self and the other' (Eisenberg and Fabes, 1990: p. 132). It also involves both cognitive and emotional processes. Empathy can be measured using self-reports, nonverbal expressions, or psychophysiological indices. Socialization influences the extent to which people experience empathy for others. Children whose mothers are empathic, warm, good at perspective taking, and comforting are more likely to become highly empathic themselves. Women report higher levels of empathy than men, even when they physiologically show similar levels of arousal.

Empathy also appears to have biological and genetic components. Empathic responses are found in most species and are present among human infants shortly after birth. Brain-imaging studies support the idea that humans are hard-wired to be empathic. The human brain contains mirror neurons, which are cells that become activated when observing others' behaviors in ways as if observers themselves were engaging in that behavior. Although there is some controversy about when and how mirror neurons function, they do represent a structure in the brain that bridges the experiences of others with people's own experience (Zaki and Ochsner, 2012). In addition, empathy is a genetically heritable trait: Identical twins have more similar levels of empathy than fraternal twins or siblings. These findings indicate that empathy is a basic human capacity and may represent a basic mechanism for translating genetic prosocial predispositions, which may have evolutionary benefits, into action.

There is substantial empirical evidence that people are fundamentally empathic and emotionally responsive to the needs of others. People are aroused physiologically and subjectively by the distress of others. This reaction appears even among very young children and occurs across cultures. In addition, people show greater empathy toward others who are closer and more similar to them.

Different kinds of empathy produce different types of responses. Cognitive empathy represents the process by which individuals are able to adopt the perspective of another person, imagining what the other person thinks and feels. When people feel that they can relate to others and adopt their perspective, they show patterns of neurological activity similar to those that occur when they personally experience such an event. Emotional empathy relates to the affective response that stems from recognizing another person's need. It is associated with psychophysiological arousal, such as increased heart-rate. How people experience that arousal emotionally – whether as sadness, personal distress, or empathic concern – depends upon the magnitude of the arousal, the closeness with the person in need, the nature of the situation, and dispositional characteristics of the observer. Some people tend to experience empathic arousal more strongly, some have more difficulty regulating their arousal once it occurs, and some people are more inclined to experience one emotion over other emotions. Although cognitive empathy typically arouses some degree of emotional empathy, people can take the perspective of others without having a significant emotional reaction. In addition, people can experience emotional empathy spontaneously, without consciously adopting the perspective of the other person. Both cognitive and emotional empathy can motivate prosocial behavior.

Research Trends

Research in the area of prosocial behavior and empathy has developed in several stages. The work of the early and mid-1960s typically focused on norms, such as social responsibility and reciprocity, which seemed to govern prosocial behavior. By the end of that decade and into the early 1970s,

 http://dx.doi.org/10.1016/B978-0-08-097086-8.24024-5

investigators, stimulated by public outrage at bystander apathy, investigated factors that reduced the likelihood of intervening in crisis and emergency situations. As researchers also explored the reasons why people *do* engage in prosocial activities, they began to consider more fully the role of empathy and developmental influences. In the 1980s, interest in prosocial actions declined somewhat and the questions moved primarily from *when* people help to *why* people help. Researchers frequently attempted to understand fundamental motivational processes, considering how different affective consequences of empathy could produce either egoistic or altruistic motivation.

Research in the 1990s provided a clearer link between prosocial motivations and general personal, social, and intergroup orientations. In the 1990s, the research also expanded its focus from spontaneous helping between individuals to more sustained and collective prosocial actions, such as donating (e.g., blood or money) or volunteering to help others, even when there is no opportunity to meet those who benefit from such actions (Wilson, 2000). Over the past decade, researchers have turned their attention to more microlevel processes, such as the brain structures and functions underlying empathy, and more macrolevel processes, such as the role of prosocial behavior in managing intergroup relations and contributing to social coordination within groups (Penner et al., 2005).

When Do People Help?

Research has identified a range of social and situational factors that influence helping and other prosocial actions (Dovidio et al., 2006). In terms of social factors, people are more likely to engage in prosocial activities for others with whom they are more closely related, are more similar, and share group membership. People are less likely to respond prosocially when others are perceived as more responsible for their plight or otherwise undeserving of assistance. With respect to situational factors, people are more likely to help in situations that are more serious and clear. They are less likely to help when they believe that others are present and will take action, which relieves a bystander from having to assume personal responsibility for intervention.

Both cognitive (e.g., norms and perceived costs and rewards) and affective (e.g., arousal and emotion) processes underlie prosocial behavior. In terms of cognitive influences, whether a person helps depends upon the outcomes of a series of decisions (Latané and Darley, 1970). People must recognize that help is needed, assume personal responsibility for intervening, decide how to help, and then take action. This model has also been applied to nonemergency situations.

Alternatively, a cost–reward analysis of prosocial action assumes an economic view of human behavior. In a potential helping situation, a person analyzes the circumstances, weighs the probable costs and rewards of alternative courses of action, and then arrives at a decision that will result in the best personal outcome. Current research is consistent with this central tenet of the cost–reward approach. In addition to cognitive processes, the arousal and affect associated with experiencing empathy for another person is a critical factor in determining when and explaining why people help others.

Empathy and Prosocial Motivation

Empathy is central to the processes that motivate prosocial action. Cognitive empathy sensitizes people to the needs of others and to the situational forces that may have produced these needs. There is a general positive association between dispositional cognitive empathy and a broad range of prosocial actions (Davis, 1994). In addition, engaging regularly in helping, such as through sustained volunteering or blood donation, can create a self-image of being empathic, which leads people to be even more prosocial in the future. Cognitive empathy in the form of perspective taking not only influences the degree of empathic arousal that people experience but also, in combination with other cognitive processes, shapes the nature of the empathic emotion that is experienced. Cognitive empathy can facilitate self-focused emotions, such as sadness or distress, or other-oriented emotions, such as sympathy or empathic concern.

Although most researchers agree that empathic arousal is an important determinant of prosocial action, there is less agreement about the nature of this emotion and how it actually motivates prosocial behavior. Empathy can produce different emotions depending on the context. In severe emergency situations, bystanders may become upset and distressed; in less critical, less intense problem situations, observers may feel sad, tense, or concerned and sympathetic (Batson, 2011; Dovidio et al., 2006).

How empathic arousal is interpreted, in turn, elicits either egoistic or altruistic motivation. Empathic arousal interpreted as personally directed emotions, such as sadness or personal distress, promotes egoistically motivated prosocial behavior, with the primary goal of relieving this unpleasant state. In contrast, empathic arousal experienced as empathic concern produces altruistic motivation, with the primary goal of improving the other person's welfare.

Empathy and Egoism

Models of egoistic motivation posit that helping is directed by the primary goal of improving one's own welfare; the anticipated benefit to others is secondary. From this perspective, empathy elicits self-oriented emotions (e.g., sadness or distress) that are experienced as unpleasant and motivate actions, such as helping, that are perceived to relieve them. Two of these approaches are the negative-state relief model and the arousal: cost–reward model.

According to the negative-state relief model (Cialdini et al., 1997), feelings of guilt or sadness motivate people to engage in behaviors that will improve their mood. Helping represents one such behavior, because people learn through socialization and experience that helping is self-rewarding. Three fundamental implications of the negative-state relief model have received support (see Dovidio et al., 2006). First, a variety of negative states, including guilt from having personally harmed a person and sadness from simply observing another person's unfortunate situation, can motivate helping. Second, other events besides helping (e.g., receiving praise) may just as effectively make people feel better, and exposure to these events can thus relieve the motivation to help caused by negative states. Third, negative moods motivate helping only if people

believe that their moods can be improved by helping. Negative feelings will *not* promote helping if people are led to believe that these feelings cannot be relieved or if, as with younger children, the self-rewarding properties have not yet developed.

Affective empathy can produce other emotional reactions, such as distress and upset, particularly among bystanders in emergencies. According to the arousal: cost–reward model (Piliavin et al., 1981), empathic arousal is generated by witnessing the distress of another person. When the bystander's empathic arousal is attributed to the other person's distress, it is emotionally experienced by the observer as unpleasant. The observer is therefore motivated to reduce it. The person then weighs various costs and rewards for helping or not helping, and chooses a course of action that relieves the unpleasant arousal while minimizing net costs and maximizing rewards. One normally efficient way of reducing this arousal is by helping to relieve the other's distress. Thus, from this perspective, arousal motivates a bystander to take action, and the cost–reward analysis shapes the direction that this action will take.

Supportive of the arousal: cost–reward model, empathic arousal attributed to the other person's situation motivates helping. Facial, gestural, and vocal indications of empathically induced arousal, as well as self-reports of empathically induced anxiety, are all positively related to helping (see Dovidio et al., 2006). Consistent with the hypothesized importance of attributing this arousal to the other's situation, people are more likely to help when arousal from extraneous sources such as exercise, erotic films, and aggressive films is attributed to the immediate need of another person. People are less likely to help when arousal generated by witnessing another person's distress is associated with a different cause (e.g., misattributed to a pill). In addition, extreme empathic overarousal or the inability to regulate empathic arousal, which may interfere with the attribution process, can reduce helpfulness.

Also consistent with the arousal: cost–reward model, people donate more money when confronted with a single, identifiable victim than a group of victims. It has been suggested that this effect may occur because people experience 'psychic numbing' (i.e., less sympathy) when they are confronted with the needs of a group of people rather than an individual. Recent evidence, though, suggests that when people do not expect to have to help the victims, they report more compassion for a group than for an individual. However, when there are financial or emotional costs to helping, people actively try to reduce their feelings of compassion for the victims (Cameron and Payne, 2011). Thus, when prosocial action becomes too demanding, people 'downregulate' their emotions and experience less emotional empathy.

Empathy and Altruism

In contrast to egoistic models of helping is the empathy–altruism hypothesis (Batson, 2011). Although this framework acknowledges that egoistically motivated helping occurs, it also posits that true altruism also exists. The primary mechanism in the empathy–altruism hypothesis is the emotional reaction to another person's problem. Empathy that is experienced emotionally as compassion and concern (i.e., as 'empathic concern') produces altruistic motivation. Because altruistic motivation has the primary goal of improving the other person's welfare, an altruistically motivated person will help if (1) helping is possible, (2) helping is perceived to be ultimately beneficial to the person in need, and (3) helping personally will provide greater benefit to the person in need than would assistance from another person also able to offer it.

Numerous experiments have produced impressive empirical support for the empathy–altruism hypothesis (Batson, 2011). Participants who experience relatively high levels of empathic concern show high levels of helpfulness even when it is easy to avoid the other person's distress, when they can readily justify not helping, when helping is not apparently instrumental to improving the benefactor's own mood, and when mood-improving events occur prior to the helping opportunity. In addition, because it motivates people primarily to improve the welfare of others, people experiencing greater empathic concern are more likely to withhold direct assistance from another person if helping (e.g., providing the answer to a problem) will interfere with the other person's longer term best interests (e.g., learning how to solve the problem themselves).

However, several researchers have proposed alternative explanations that challenge the contention that helping can be altruistically motivated. These explanations have focused on (1) how feelings of empathic concern may be associated with special costs for not helping or rewards for helping, (2) how feelings of sadness that are aroused along with empathic concern actually are the primary determinants of helping, and (3) how manipulations used to induce empathic concern for another person also create a greater sense of self-other overlap, or 'oneness,' so that helping may also have direct and primary benefits for the helper (see Cialdini et al., 1997). Nevertheless, despite the critiques and controversies about aspects of the empathy–altruism hypothesis, the preponderance of evidence from more than 30 years of experimentation on this question strongly suggests that truly altruistic motivation may exist and that all prosocial behavior is not necessarily egoistically motivated.

Empathy, Prosocial Behavior, and Intergroup Relations

Recently, researchers have focused on understanding prosocial behavior that occurs between members of different groups. In contrast to helping members of one's own group, helping members of other groups may be inhibited by intergroup biases. In general, people feel more positively about members of their own group than members of other groups, and they empathize, cognitively and emotionally, more with them. Also, people are more willing to help members of their own group than members of a different group.

For empathy to occur, people need to feel a sense of attachment to the person in need. People more readily feel a greater sense of attachment to members of their own group than members of other groups. In addition, empathy more strongly predicts helping behavior when the recipient and giver of help belong to the same group than when they belong to different groups. Instead, attraction and liking are better predictors of helping toward members of other groups (Sturmer et al., 2006).

Although the research shows that, because of intergroup bias, people generally spontaneously experience less cognitive and emotional empathy for members of another group than of their own group, and consequently are less likely to engage in prosocial behavior to benefit them, empirical evidence also reveals that *evoking* empathy for outgroup members can decrease intergroup bias. Cognitive empathy (perspective taking) reduces stereotyping of members of another group, reduces blame for their disadvantage, and increases recognition of discrimination faced by members of the group (Todd et al., 2012). Recognizing discrimination is an important step in motivating action to redress injustice. Thus, facilitating recognition of discrimination through perspective taking increases support for policies, like affirmative action, that benefits the members of another group.

Emotional empathy also improves attitudes toward members of another group. When Whites focus on the emotions of Blacks, rather than being objective, as they view episodes of racial discrimination, they experience greater moral outrage and exhibit reduced intergroup bias and increased willingness to take prosocial action for Blacks. In addition, focusing on the emotions of members stigmatized groups as they describe their needs and problems arouses emotional empathy in the form of empathic concern, which in turn improves attitudes toward the entire group (Batson, 2011).

Cognitive and emotional empathy also play critical roles in how intergroup contact increases positive attitudes toward members of other groups. The contact hypothesis, which proposes that intergroup group under specified conditions (e.g., cooperative interaction and common goals) can improve attitudes toward other groups, is one of the most widely researched frameworks for intergroup relations. A *meta-analysis* of hundreds of studies indicated that intergroup contact improved attitudes toward other groups largely because it increased both perspective taking and feelings of emotional empathy toward these groups and their members (Pettigrew and Tropp, 2008).

Helping Behavior and Intergroup Power Relations

Whereas empathy promotes prosocial actions to benefit recipients, helping behavior motivated by other factors can be manipulative, improving the benefactor's status and decreasing the longer term welfare of the recipient. According to the intergroup helping as status relations model (Nadler, 2002), members of higher status groups are motivated to maintain their group's status, whereas members of lower status groups seek to improve their group's status. These motivations affect willingness to give and receive help. Specifically, members of high-status groups may help lower status groups, in part, to maintain the status hierarchy. They are likely to offer assistance, particularly when they feel that their group's superior status is insecure, that increases the dependency of the other group on their group (e.g., providing complete answers for task) but not empowering forms of help (e.g., offering a hint that will help others learn the answer on their own).

Members of low-status groups, who strive to enhance the position of their group, tend not to seek dependency-oriented help from the high-status group and react negatively when such unsolicited assistance is offered. Members of the lower status group may resist such help because they do not wish to reinforce their group's inferiority and dependence on the higher status group. Thus, whereas empathy typically motivates people to think more positively about, and act prosocially to benefit, members of other groups, helping exchanges in the absence of empathy can, in some cases, operate to decrease the welfare of the recipient's group while enhancing the power and superior position of the helper's group. Helping behavior is not always synonymous with prosocial behavior.

Conclusion

Empathy is a basic human capacity that is one of the most important motivators of prosocial behavior, which is the behavior that intended to benefit others. Cognitive empathy involves adopting the perspective of another person, whereas emotional empathy relates to the affective response that occurs when people perceive another person's need. Both forms of empathy are prevalent across all human cultures. Individual differences in empathy are determined by genetic, biological, environmental, and socialization processes.

The social context, the nature of the situation, the characteristics of the person in need, and the personality of the potential helper not only affect assessments of costs and rewards and the decisions about whether to engage in prosocial acts, but also shape empathic responses. People display higher levels of prosocial behavior toward others who are similar to them, are members of their group, or who are in greater need, and they do so because they experience higher levels of empathy under these conditions. In addition, how empathy is experienced emotionally is fundamental; empathy can produce either egoistic motivation, intended to improve one's own or their group's welfare, or altruistic motivation, with the goal of improving others' welfare. Experiencing cognitive and emotional empathy improves intergroup relations, but helping motivated by factors other than empathy can reinforce power disparities and intergroup bias. Thus, cognitive and emotional empathy plays critical roles in creating and maintaining positive, productive, and mutually beneficial interpersonal and intergroup relations.

Prosocial Behavior during Adolescence

Aerika S Brittian and Marisha L Humphries, University of Illinois at Chicago, Chicago, IL, USA

Abstract

Prosocial behaviors are an aspect of adolescents' positive development that has gained greater attention in the developmental literature since the 1990s. In this article, the authors review the literature pertaining to prosocial behaviors during adolescence. The authors begin by defining prosocial behaviors as prior theory and empirical studies have done. They describe antecedents to adolescents' prosocial behaviors with a focus on two primary factors: *socialization* and *cultural orientations*. Accordingly, the authors review prior literature on prosocial behaviors among different ethnic/cultural groups throughout this article. As limited studies have examined prosocial behaviors among some specific ethnic groups, the authors conclude with recommendations for future research.

Adolescence is a period of human development marked by several biological, cognitive, and social transitions. Physical changes, such as the onset of puberty and rapid changes in body composition (e.g., height, weight, and sex characteristics) prompt adolescents to engage in greater self-exploration (McCabe and Ricciardelli, 2003). Enhanced cognitive abilities permit adolescents to engage in more symbolic thinking and to contemplate abstract concepts, such as the self and one's relationship to others (Kuhn, 2009; Steinberg, 2005). Furthermore, adolescence is marked with increased responsibilities at home and in the school context, opportunities for caregiving within the family, and mutuality in peer relationships (American Psychological Association, 2008). Moreover, society demands a greater level of psychosocial maturity and expects greater adherence to social norms from adolescents compared to children (Eccles et al., 2008). Therefore, adolescence presents itself as a time of major life transitions. In light of these myriad transitions, adolescents are further developing *prosocial behaviors*.

Although the emergence of prosocial behaviors (e.g., expressed behaviors that are intended to benefit others) begins in early childhood, the developmental transitions described above allow adolescents to become active agents in their own developmental process. Behavior that is motivated by adolescents' concern for others is thought to reflect optimal social functioning or prosocial behaviors (American Psychological Association, 2008). While the early literature focused primarily on prosocial behaviors among young children (e.g., Garner, 2006; Garner et al., 2008; Iannotti, 1985) there are several reasons to track prosocial development into adolescence. First and foremost, individuals develop cognitive abilities that allow them to better phenomenologically process and psychologically mediate life experiences that may facilitate (e.g., completing household chores and caring for siblings) or hinder (e.g., interpersonal conflict and perceptions of institutional discrimination) prosocial development (e.g., Brown and Bigler, 2005). Adolescents express more intentionality in which activities they will engage in and become selective in where they choose to devote their energies (Mahoney et al., 2009). Finally, adolescents are afforded more opportunities to express helping behaviors in other social spheres beyond the family context, such as in schools, communities, and civic society (Yates and Youniss, 1996).

Origins and Definitions of Prosocial Behaviors

Since the turn of the twenty-first century, there has been growing interest in understanding the relationships that exist between the strengths of individuals and resources within communities (e.g., person ↔ context) in order to identify pathways for healthy development, or to understand how adolescents' thriving can be promoted. This line of thinking is commonly described as the positive youth development perspective (e.g., Lerner et al., 2009). Although the adolescent literature still predominantly focuses on problematic development (e.g., delinquency and risk-taking behaviors), studies on adolescents' prosocial development have increased substantially since the 1990s (Eisenberg et al., 2009a), paralleling the paradigm shift from a deficit-based model of development to one focusing on positive attributes of youth (e.g., Benson et al., 2006; Lerner, 2005).

Generally described as the expression of voluntary behaviors with the intention to benefit others (Carlo, 2006; Eisenberg, 2006; see full review by Eisenberg et al., 2009a), prosocial behavior is one aspect among others of positive adolescent development that is gaining greater attention in the literature. Theory on prosocial development is rooted in the literature on moral development, which includes cognitive aspects of moral reasoning (e.g., how individuals decide between moral dilemmas; Kohlberg, 1978), moral behaviors (e.g., expression of behaviors that benefit society; Eisenberg and Fabes, 1998), and emotions (e.g., empathy; Eisenberg and Fabes, 1990).

Empirical studies on adolescents' prosocial development have found that different types of prosocial behaviors may exist. For example, Carlo and colleagues (e.g., Carlo et al., 2010; Carlo and Randall, 2002) found six types of *prosocial tendencies* (intentions to help others): *compliant*, *dire*, *emotional*, *altruistic*, *anonymous*, and *public*. Compliant helping refers to an individual's intent to assist when asked. Emotional helping refers to helping in emotionally evocative situations (e.g., witnessing another individual crying). Dire helping refers to

intentions to assist in emergency situations. Altruistic helping refers to a person's intention to help with no expectation of reward. Anonymous has been described as helping without anyone knowing. Finally, public helping has been described as intentions to help when others are watching. Research on these types of prosocial tendencies indicates that some behaviors are more related to each other than others. For example, Calderón-Tena et al. (2011) found that compliant, emotional, and dire helping may be related positively to one another, while other studies suggest that altruistic helping may be different from other types of prosocial tendencies (e.g., Brittian et al., 2013).

Research indicates that adolescents evaluate the situational context when determining whether to engage in prosocial behavior (e.g., Tisak et al., 2002). Some youth who engage in high levels of public prosocial behavior may do so out of self-interest needs rather than for the benefit of others. For instance, in a study of largely Caucasian adolescents, *proactive prosocial behavior* (e.g., behaving prosocially to benefit the self) was the only type of prosocial behavior that was related to aggressive behavior. Specifically, adolescents who reported positive or normative beliefs about engaging in aggressive behaviors were more likely to engage in proactive prosocial behaviors, and were less likely to engage in altruistic helping and reactive aggressive behaviors (Boxer et al., 2004). Proactive prosocial behavior requires more socially sophisticated and manipulative conceptualizations of behaviors (Boxer et al., 2004). In this particular study, adolescents who endorsed retaliatory aggressive beliefs were more likely to engage in proactive prosocial behavior. This suggests that prosocial behaviors that are self-serving may be facilitated by motivations that are similar to those that facilitate aggressive behavior. If this is true, then perhaps the label prosocial behavior is inadequate or inappropriate for these types of self-serving behaviors since the behavior is not based on helping others, but rather is motivated by satisfying the needs of the self. More importantly, what does it mean to engage in prosocial behaviors for the benefit of the self? Does it yield differential effects for adolescents? Do these types of behaviors still serve as a protective factor against challenging or problematic experiences? These questions not only have research implications, but applied implications as well. For instance, educators and providers have to consider how and what types of prosocial behaviors are promoted through programs, in schools, and by parents and caregivers.

The expression of prosocial behaviors also varies by demographic and developmental characteristics, such as gender and age. In general, adolescent girls are more likely to exhibit prosocial behaviors compared to adolescent boys (e.g., Hastings et al., 2007). However, some studies have observed that boys engage in more public helping (e.g., helping when one is being observed; Carlo and Randall, 2002). More helping behaviors among girls may reflect that girls are socialized to be more caring and nurturing and to exhibit greater levels of concern for others (Eisenberg et al., 2009). Divergent from other studies on prosocial behavior that found gender differences, McMahon et al. (2006) reported that African-American boys exhibited more prosocial behaviors than African-American girls. Therefore, gender differences in prosocial behaviors may vary among US adolescents based on cultural differences (Eisenberg and Morris, 2004) as well.

The literature on prosocial behaviors and ontogeny has yielded mixed age difference findings depending on the type of prosocial behavior assessed. Some research (Carlo and Randall, 2002; Fabes et al., 1999) contends that older adolescents engage in more prosocial behaviors while other research has noted mixed findings. In general, older children have more advanced prosocial skills typically due to increased empathetic and perspective taking abilities, and increased and nuanced opportunities for social interactions (Kokko et al., 2006). In addition, some types of social interactions run counter to each other. For example, individuals on average tend to become more prosocial and less competitive and individualistic across the life span (Van Lange et al.,1997). Differential findings have shown that prosocial behaviors decrease in late adolescents, while other researchers have not found age differences among adolescents. For example, there is some research that revealed a declining trend in prosocial behavior when children are assessed longitudinally using the same forms of measurement (Kokko et al., 2006; Côté et al., 2002). Therefore, it is unclear whether the decline in prosocial behaviors observed was due to developmental changes as adolescents mature or were attributed to issues of measurement (i.e., measurement of prosocial behavior across time is not robust enough to detect developmental changes). Due to mixed findings, future research needs to explore gender and developmental age changes in a more sophisticated way that examines the intersectionality of these two demographic issues (gender and age) along with the role of culture.

Antecedents to Prosocial Behavior

Adolescents' prosocial behaviors do not develop void of contextual influence. Youth are part of a larger system, involving family, peers, school, societal values, and the historical context (Bronfenbrenner, 2005). Indeed, research describes two major contextual factors that foster prosocial behaviors: *socialization* and *cultural orientations*.

Socialization

Socialization is the process through which individuals acquire beliefs, values, social norms, and practices that allow them to successfully interact with society (Göncü and Gauvain, 2012; Rogoff, 2003). Parents represent a key socializing agent through which adolescents learn to express prosocial behaviors (Carlo et al., 2007). One direct way that socialization relates to prosocial behaviors is through parenting practices. A study by Carlo et al. (2011) found that parents' socialization, measured as parental inductions (e.g., degree of positive reasoning and explanations that parents use with their adolescent) played a significant role in promoting sympathy among adolescents, consequently promoted prosocial tendencies indirectly; however, no significant ethnic differences in these associations were found between Mexican-American and Caucasian adolescents who participated in the research. A multicultural study by Shen

et al. (2013) indicated that inductive parenting practices were positively related to moral development indirectly through empathy among Caucasian, Mexican-American, and Taiwanese adolescents. Interestingly, the aforementioned study reported that parenting practices were related to sympathy but not perspective-taking among Mexican-American and Taiwanese adolescents compared to Caucasian adolescents. Researchers noted that more studies are needed across cultural groups to understand why these cultural differences were observed.

In addition to direct socialization (e.g., talking to adolescents about helping others), adolescents may acquire prosocial behaviors through informal social learning (Lave and Wenger, 1991), where parents model behaviors and youth observe how parents interact with other members of society. Certainly, some research indicates that adolescents are likely to engage in helping behaviors with parents, such as volunteering and community service (e.g., Fletcher et al., 2000). These activities may or may not continue throughout adolescence, as youth form their own goals and interests.

Peers represent another prominent social context for adolescents' prosocial behaviors. Wentzel et al. (2007) found that peers played an influential role in adolescents' prosocial behavior. Specifically, adolescents' perceptions of their peers' expectations regarding prosocial behavior was significantly related to the adolescents' engagement in actual prosocial behaviors at school. Important note, researchers indicated that the racial demographics of the school may have influenced this effect. In this case, peer influence on adolescents' behavior appeared to be influenced by whether the student attended a school where his or her racial group represented the majority of the student population. Peer influences are typically discussed in terms of negative or antisocial influences; however, this research provides initial support for the positive influence that peers can have on adolescents' developmental outcomes, mainly prosocial behaviors. Although further research is needed to unpack this finding, these findings do highlight the positive influential role of peers in adolescents' development.

Socialization of prosocial behaviors can occur in more indirect ways than social modeling. Mainly, adolescents' perceptions of their parents and peers' perspectives on prosocial behavior can also have a significant impact on adolescents' prosocial behaviors. For example, adolescents' perceptions of parental and peer prosocial behavioral norms, assessed as parents and peers approval or disapproval of their participation in problem behaviors, emerged as protective factors in reducing risk factors associated with American Indian youth's engagement in violence in an urban context (Bearinger et al., 2005). While the literature on cultural variations of socialization and adolescents' prosocial behavior is limited, there is evidence to suggest that the environment that parents create and parents' expectations for service, as well as peer culture, are directly and indirectly related to the development of adolescents' prosocial behaviors.

Cultural Orientations

It has been well documented that culture influences children and adolescents' development (Rogoff, 2003); however, less is known about the relationship between culture and positive aspects of adolescent development, such as prosocial behaviors. Systematic research on the development of prosocial behaviors among youth from diverse cultural backgrounds is underdeveloped and rarely explored (Humphries and Jagers, 2009). The use of a cultural framework or perspective to understand adolescents' prosocial development acknowledges that human development is situated in and is influenced positively by cultural values, traditions, and institutions (American Psychological Association, 2008).

This section reviews research in two main contexts where studies elucidate how culture intersects with prosocial behaviors among adolescents: (1) communal/collective orientations and (2) religious/spiritual orientations. Both cultural orientations have been examined in relation to prosociality. First, the authors will discuss the literature on communalism/collectivism, followed by religiosity/spirituality.

Communal/Collective Orientations

Research on collective and communal orientations and prosocial behaviors among minority youth dates back to the 1970s. Knight and Kagan (1977) observed that Mexican-American children (ages 5–9 years) expressed more prosocial behaviors compared to Anglo-American children who exhibited higher levels of individualism and competitiveness. Researchers currently posit that collaboration, a group or communal orientation, is a central feature of Mexican-American cultural orientation that promotes prosocial behaviors (Knight and Carlo, 2012). Several contemporary studies have sought to understand how cultural factors relate to the development of prosocial tendencies among Latino adolescents (e.g., Armenta et al., 2011). For example, a study by Schwartz et al. (2007) found that an orientation toward Hispanic culture was positively related to Latino early adolescents' prosocial behaviors. Calderón-Tena et al. (2011) found that Mexican-American cultural values, assessed as *familism* (e.g., respect for elders and family obligations), were positively related to Mexican-American adolescents' prosocial ideas. Moreover, Armenta et al. (2011) observed that Mexican-American cultural values (assessed as types of familism values) were positively related to several types of prosocial tendencies (e.g., compliant, emotional, dire, and anonymous) compared to mainstream American values (assessed as self-reliance, material success, and personal achievement) that related to more public helping and less altruistic helping.

Ward (1995) contended that the dominant culture in the United States negatively impacts African-American adolescents' positive development. Mainly, she asserted that the excessive focus on autonomy of the individual and the preoccupation with and competition for consumption of materialism is thought to erode prosocial behaviors among African-American adolescents. Moreover, she argued that American mainstream cultural values of *individualism* and *materialism* actually run counter to the cultural orientations of African-Americans, which includes *communalism* and *religiosity/spirituality*.

Communalism implies an awareness of the fundamental interdependence of others with a premium being placed on

social bonds and group obligations (Boykin et al., 1997). This specific cultural orientation places the needs of the group before those of the individual. Studies on African-Americans have found that communalism is related positively to correlates of African-American adolescents' prosocial behaviors, including empathy (Humphries et al., 2000; Jagers et al., 2007) and moral reasoning (Humphries et al., 2000; Woods and Jagers, 2003). Humphries et al. (2000) observed that communalism emerged as a significant predictor of moral reasoning among African-American fifth and eighth grade boys, but not among African-American girls. This gender by culture finding was surprising given that African-American girls in the study reported higher communalism scores and seemed to resonate to a communal orientation more so than their male counterparts. Therefore, more research is needed to understand the intersection between aspects of culture, such as communalism, and gender among African-American youth.

This is not to suggest that a communal or collective orientation is uniquely associated with African-Americans. Research indicates that other cultural groups that utilize a collective or community-focused frame of reference exhibit similar associations with prosocial behaviors. For example, similar patterns of association have been found among Native American youth. Reservation living, even in the context of intergenerational poverty, may provide Native American youth with a source of support and protection facilitating their positive development. Specifically, LaFramboise et al. (2006) noted that community support, maternal warmth, and enculturation (orientation toward one's culture of origin) emerged as protective factors for Native American early adolescents living on a reservation. Notably, the majority of youth in this study (over 60%) were characterized as prosocial while avoiding problem behaviors (LaFramboise et al., 2006).

Religious/Spiritual Orientations

Many studies have acknowledged the positive association between religious/spiritual orientation and prosocial behaviors (e.g., Furrow et al., 2004; Jagers and Mock, 1993; Johnson, 2008; King and Benson, 2005). Some research indicates that religious orientation serves as a type of social control by discouraging risky behaviors among adolescents, including substance use and delinquency (e.g., Brittian et al., 2013; Wallace and Forman, 1998). Most religions encourage adolescents to think beyond themselves, bolster concern for others well-being, and promote development of a broader worldview (Furrow et al., 2004; King, 2003). Moreover, it has been suggested that many religions are associated with prosocial behaviors due to an emphasis on helping others, service to the community, and promoting a collective orientation (Saroglou et al., 2004; Eisenberg et al., 2011). Furthermore, a spiritual or religious orientation requires the belief in a higher being and a conceptualization that connects the individual to this higher being. Therefore, this relationship requires perspective taking, a skill that is necessary for optimal social development and implementation of prosocial ideas and behaviors.

Research on adolescent populations from various cultural groups has yielded findings that support the association between religious/spiritual orientation and prosocial behaviors. In a diverse sample of youth, involving largely Latino adolescents, religious identity was associated with prosocial beliefs and attitudes (Furrow et al., 2004). A significant association was found between religiosity and certain types of prosocial behavior for Caucasian adolescents (Hardy and Carlo, 2005). Specifically, Caucasian adolescents who reported higher levels of religiosity were more likely to engage in altruistic, compliant, and anonymous forms of prosocial behaviors. Eisenberg et al. (2009b) found that cross-religious friendships were a significant factor for Indonesian adolescents' socioemotional functioning and prosocial behaviors at school. Moreover, French et al. (2008) observed that religious involvement was positively related to prosocial behaviors among eighth and ninth grade Indonesian Muslim youth, and researchers attributed this positive association to the collectivistic nature of religion. Similarly, a longitudinal study of Italian adolescents indicated that religious coping was predictive of more prosocial behaviors (Eisenberg et al., 2011).

Finally, spirituality and religion are important cultural dimensions that are present in African-American culture and the everyday lives of African-American people (Mattis and Jagers, 2001; Taylor et al., 2004). A longitudinal study by Smetana and Metzger (2005) found that African-American adolescents' religious and spiritual beliefs were longitudinally predictive of their community involvement and engagement in prosocial behaviors 3 years later. This overall body of research provides further evidence for the need of future studies to examine particular types of prosocial behaviors and attitudes as they relate to religiosity and spirituality among adolescents in order to gain a better understanding of the associations between this cultural orientation and positive development.

Methodological Issues and Future Directions for Research

One persistent question that remains unanswered in the literature is around intentions to engage in helping behaviors. Some research attempts to address this question. For example, prior literature indicates that, in general, youth are more likely to assist close friends than acquaintances or strangers (Tisak et al., 2002). In addition, some studies have found that an adolescent's willingness to engage in prosocial behaviors may be influenced by the cultural background of the 'other.' Specifically, adolescents may be more willing to direct prosocial actions toward those who share their same cultural background; this has been found among studies with children (e.g., Zimmerman and Levy, 2000; Zinser et al., 1981). Furthermore, this issue may be complicated by whether the adolescent is in an environment where his or her cultural group is in the majority or minority (e.g., Eisenberg et al., 2009). Therefore, future studies should consider how the target of one's prosocial behavior influences intentions to help in various social situations.

In addition, some critical areas around conceptualization (e.g., definition) and measurement of prosocial behaviors as they relate to cultural groups exist. For example, some studies may assess volunteerism or civic engagement among adolescents (e.g., Hart et al., 2007), but may not specifically describe

these actions as prosocial behaviors. For example, Sherrod and Lauckhardt (2009) posit that the literature on civic engagement has yielded mixed findings with regard to minority youth. It appears that culture and ethnicity influence adolescents' prosocial behaviors but in complex ways (e.g., Carlo et al., 1999). In addition, it may be difficult to distinguish how ethnicity and race independently influence adolescents' prosocial development since these characteristics are often confounded with social class (Sherrod and Lauckhardt, 2009). In this case, more within-cultural group investigation is needed. Furthermore, when studies account for the availability of opportunities to engage in prosocial behaviors, research findings become more complicated (Balsano, 2005). For this reason, it is possible that some of the differences observed in previous studies can be attributed to definition and measurement of prosocial behaviors. Therefore, more research is needed to understand how culture intersects with other demographic characteristics (e.g., income) to influence prosocial behaviors among adolescents.

Emerging literature indicates that negative social experiences, such as perceived interpersonal and institutional discrimination, pose a significant threat to prosocial development (e.g., Brittian et al., 2013; see also Sherrod and Lauckhardt, 2009). However, other research suggests that a strong sense of fidelity (e.g., the ability to maintain prosocial values in spite of societal contradictions; Erikson, 1965) may lead to prosocial behaviors, if adolescents commit to social groups and institutions. For example, if a young person feels strongly and positively about his or her cultural group and perceives that his or her group is treated unfairly in society (e.g., perceived institutional discrimination), he or she may choose to engage in social and political arenas in order to improve the conditions for his or her cultural group (e.g., O'Leary and Romero, 2011). This type of prosocial behavior may be described as a precursor to engagement in social justice among adolescents (e.g., Ginwright, 2007) or a form public helping. Brittian et al. (2013) found that perceptions of ethnic discrimination were indirectly related to public helping among Mexican-American adolescents through a direct relationship with Mexican-American cultural values. O'Leary and Romero (2011) found instantiations of increased civic engagement in response to an antiethnic studies government bill among Mexican descent students' and this type of 'public' helping served as a protective factor for students' mental health. Therefore, future studies should further investigate factors that impede prosocial behaviors among minority adolescents and continue to explore conditions through which prosocial behaviors occur in spite of these perceived challenges.

Conclusions

Although research on adolescents' prosocial behaviors has burgeoned significantly over the past 20 years, there are several areas that the literature can be advanced. Despite the relative growth in research examining adolescents' prosocial behaviors in general, research on cultural groups is scarce, with notable exceptions described in this article. In addition, several areas were elucidated that promote adolescents' prosocial behaviors (e.g., parent and peer socialization, and cultural orientations) that warrant further investigation.

Prosocial Behavior during Childhood and Cultural Variations

Stuart I Hammond, Whitney Waugh, Emma Satlof-Bedrick, and Celia A Brownell, University of Pittsburgh, Pittsburgh, PA, USA

Abstract

Children's prosocial behaviors include acts such as sharing, helping, comforting, cooperating, and can come to involve complex behaviors such as lying to protect someone's feelings. Because prosocial behaviors are performed for diverse reasons, both moral and nonmoral, research findings on prosociality in children are complex, although clear age trends are present. A variety of theories attempt to explain children's prosocial development, each providing insights into certain aspects. Although cultural influences are evident throughout the development of prosocial behavior, future research will need to untangle the true significance of these influences.

Understanding Prosocial Behavior

Defining Prosocial Behavior

Children's prosocial behavior encompasses a diverse range of behaviors that can include mundane acts like sharing toys with friends, remarkable acts like helping someone who is hurt or incapacitated, and even some very sophisticated acts like lying to protect another's feelings. The commonality that binds these behaviors together is that they are performed with the intention to benefit another person (e.g., Eisenberg et al., in press). However, beyond this point of cohesion, children's prosocial behaviors are marked by tremendous diversity, in type, motivation, and cause.

Researchers have long recognized that both moral motivations, such as an altruistic act produced solely for the good of another, and nonmoral motivations, such as positive acts to please a parent, to gain social status, or to maintain a friendship underlie prosocial behavior (Bierhoff, 2002). Prosocial behaviors are also diverse in their mechanisms. To the extent that prosocial behavior in children is thought to reflect a single unified construct, the findings of the larger body of research on prosocial behavior can seem disappointingly inconclusive or even baffling. For example, in younger children, some prosocial tendencies are correlated with aggressive tendencies, a seeming paradox (e.g., Persson, 2005). Considered more closely, these findings may reflect the fact that some children are skilled in using both instrumental aggression and instrumental prosocial acts to their benefit, in order to get other children to like them or do what they want. In yet other cases, it can be that children with poor impulse control, or even those who are more assertive, may be more likely to both help and harm others. Similarly, in terms of gender, although girls are thought to be more prosocial than boys, and do seem to have higher levels of self-reported compassion for others, actual findings in this area are mixed (see review in Eisenberg et al., in press). Differences tend to be stronger in survey data (self- and other-reported) and much more modest in observational or experimental data. These findings could reflect factors such as a greater assertiveness in boys, and thus a greater likelihood to engage in certain forms of prosociality.

Prosocial Development

A further complexity in understanding prosociality in the childhood years centers on the issue of development and transformation. Children's prosocial behavior lies at the intersection of early-developed action patterns and emerging social cognitive and social emotional capacities (Eisenberg et al., in press). Infants begin to display prosocial behaviors soon after their first birthday, such as sharing food or toys with a parent (Hay and Cook, 2007). As children go on to develop greater motor and physical competency, advance in social, cognitive, and affective understanding, encounter novel social situations such as in school and other community contexts, and become subject to new expectations from parents, peers, and teachers, their prosociality is further transformed (Eisenberg et al., in press).

Although at a general level prosocial behavior becomes more frequent and more reliable in older children, across cultures, developmental changes may vary the frequency of particular prosocial acts. For example, some prosocial behaviors may diminish as the motivation driving them declines or changes. Infants may help a parent with 'fun' activities such as setting the table because they are interested in taking part and because they enjoy spending time with the parent (Rheingold, 1982). With development, this activity might be seen increasingly as a boring chore, and children accordingly become less likely to help spontaneously. However, children may develop new motivations for these same prosocial behaviors, such as a desire to please their parent, receive an allowance, or because they perceive the chore as their responsibility. Or perhaps parents will no longer invite them to do this particular task, instead assigning a task such as caring for a pet.

As they develop, children also begin to view certain behaviors as inappropriate or unnecessary, whether due to recognition of social norms or to more accurate social perception. For example, older children become less likely to aid a stranger spontaneously, perhaps out of social propriety or because they can more accurately judge that a person does not always need help. Whereas infants' 'help' in the home is often viewed with irritation and exasperation by parents, because of the low competency of their prosocial behavior (Rheingold, 1982), children may come to learn prosocial behavior 'by omission,' recognizing that they have a responsibility to keep their rooms clean or keep out of their parents' way (Klein et al., 2009).

With the emergence of more advanced social capacities, children also begin to display novel forms of prosocial behavior. For example, although children are typically socialized to tell the truth but sometimes lie to hide wrongdoings,

 http://dx.doi.org/10.1016/B978-0-08-097086-8.23182-6

they may also come to learn that the truth may actually be hurtful, such that in some instances, such as receiving a disappointing gift, lying may actually be considered prosocial (e.g., Williams et al., 2013). With development, children become more competent prosocial actors, but the meaning and causes of their actions are also transformed, rendering it somewhat difficult to identify simple developmental trends.

Research and Practice

Researchers have focused the bulk of their empirical efforts on the relation of prosociality to more positively viewed psychological characteristics, particularly ones typically regarded as moral, such as caring for others and altruism, and less on the relation of prosocial behavior to factors such as status-seeking. This reflects in part an everyday valuing of morally driven prosociality, as well as the practical concern of promoting prosocial behaviors in applied and educational contexts, both as a means of promoting social harmony and good citizenship and as a means of reducing antisocial behaviors, such as bullying and aggression (e.g., Jennings and Greenberg, 2009). Despite these well-intended efforts, developmental trends raise challenging questions about the status of prosocial behavior and its relation to morality. Although prosocial behavior is often taken as an unalloyed good, and associated with positive development, the true developmental picture is more complicated. Some prosociality is associated with undesirable social and psychological characteristics and conversely, while some prosocial behavior, such as prosocial lying, may be prosocial in intent, its overall moral status is sometimes difficult to gauge.

Theories of Prosocial Development

There is no single dominant theoretical account of prosocial behavior. Rather, the major theories of prosocial development each make important contributions to different aspects of our understanding of children prosocial behavior and different areas of prosocial development.

Cognitive Developmental

The cognitive developmental moral theories of prominent figures such as Piaget, Kohlberg, and Turiel (Lapsley, 1996) are generally more concerned with the development of moral reasoning and moral motivation than with prosocial action. Traditional cognitive developmental theory has placed a heavy emphasis on the development of autonomous moral reasoning, in large part because Piaget's (1965) seminal work grew out of a reaction to the sociologist Durkheim's view of the imposition of moral norms on children by society. As a legacy of this reaction, prosocial behavior that originates in the commands and directives of a parent is regarded as somewhat detrimental to the child's moral development, although this is as much an issue of power relations in communication and parents can adopt more cooperative communicative styles. Conversely, cooperative interactions among peers, such playing games together, are thought to occur in the context of equality and mutual respect and to foster the child's autonomous reasoning and moral development.

Cognitive-developmental theories do not, in and of themselves, map out a clear pathway to the development of prosocial behavior and at least in the case of Piaget's theory, the primary question is the inverse: how moral reasoning emerges out of early prosocial interactions (Carpendale, 2009). Nevertheless, numerous studies have shown that children's prosocial behavior is positively, though modestly, associated with more advanced levels of moral reasoning (Eisenberg et al., in press).

Empathy

Empathy, an affective response that arises from comprehending the emotional state or condition of another, is thought to be a major factor in children's prosocial behavior. Research on empathy fixes motives for prosociality in other-oriented emotionality. Through the process of empathy, when children see another's emotion, usually a negative emotion such as sadness, they come to feel that emotion and are thereby motivated to help the other person (Hoffman, 2000). With development, children are able to empathize with broader features of another's situation, including imagining what someone might be feeling (e.g., after hearing about a natural disaster in another country) and becoming motivated to help (e.g., collecting donations).

Empathy is sometimes distinguished from sympathy, or showing concern for another without necessarily comprehending their emotional state and personal distress, or distress caused by the sight of another's suffering. Both empathy and sympathy are positively correlated with prosociality, and appear to become more so with age (Eisenberg et al., 2013). However, the route from a shared emotional state to actual prosocial action has long bedeviled researchers (Penner et al., 2005). One reason for this difficulty is an overwhelming focus on negative emotions such as sadness and pain, and correspondingly on prosocial behavior such as helping those who are upset are hurt. These situations are probably in the minority as compared to the amount of prosocial behaviors such as sharing and cooperation that occurs in positive and happy interactions (Brownell et al., 2002). Nevertheless, recent research on empathy has renewed interest in the role of emotions, emotion understanding, and other social cognitive capacities in the development of prosocial behavior.

Biological

Biological theories of prosocial behavior come in two principal forms. The first explores prosocial behaviors as a function of human and mammalian evolution. Earlier strands of this research generally focused on the paradox between selfish and self-maximizing behavior, necessary for reproductive success, and the existence of altruism, which reduces one's own reproductive success. Sacrificing or risking one's own life or well-being for another's means fewer of one's own (altruistic) genes survive in the gene pool, making the existence of altruism in a population difficult to explain. However, the paradox was ultimately resolved by theory and empirical findings showing that organisms are more likely to aid kin than nonkin.

More recent research, has attempted to demonstrate empirically that altruistic forms of prosociality are widespread in both humans and other mammals, and to provide plausible theories

about how prosocial behavior could have evolved (e.g., Tomasello and Vaish, 2013). To the extent that this research has aimed to show that prosociality is innate or unlearned, it has tended to focus on infants, who are, at least to a certain line of thought, not yet influenced by society or culture.

A second class of biological theories explains prosocial behavior with reference to neuropsychological development, and how individual differences in biological factors such emotional reactivity and empathy may be related to prosocial development (Eisenberg et al., in press). There does not seem to be a particular brain region associated with prosocial behavior, which given its diverse causes and motives, is perhaps unsurprising.

Evolutionary and biological theories are generally not geared toward explaining the developmental changes in prosociality that occur during childhood, although some recent studies have attempted to explore how children move from early cooperation and helping to more norm-driven forms of prosociality, such as making sure others follow rules (Tomasello and Vaish, 2013).

Social Learning

Social learning theories explore the social and interactional factors that play a role in prosocial development. Social learning theories place a heavy emphasis on the actors besides the child, particularly parents and peers, but also teachers, as well as larger social systems, such as schools and communities (Spivak and Howes, 2011). Nevertheless, parents remain an important focus of the literature, and particularly how parenting style, parental discipline techniques, and other socialization techniques are related to children's prosocial behavior (Grusec et al., 2013).

Although early social learning theory has in the past favored a unilateral transmission model of prosociality from parent and the larger society to the child, converging in some ways with the sociological model that Piaget sought to reject, more recent research has stressed a bidirectional developmental relation between the child and others. For example, as children display certain prosocial behaviors such as cleaning up in the context of play and spontaneous interaction, their parents may (or may not) come to expect these behaviors of the child. However, the child may also respond to the parent's bids in various ways, such as by disobeying parental requests for these acts, or differentially responding based on how the parent solicits cooperation (Grusec et al., 2013).

Cultural Factors in Prosocial Development

Framing Cultural Issues

Recent research on children's prosocial development has sought to explore cross-cultural differences. Cultural influences can arise at many points in children's prosocial behavior, not only in the way adults socialize prosocial behavior directly and indirectly, but also in the way that cultural tools and technologies afford particular behaviors. For example, societies with formal school systems radically change the types of interactions children have on a day-to-day basis, hence the opportunities, expectations, and demands for prosocial behavior.

Culture can be viewed as an additional influence on prosocial development that might influence differences in the frequency or timing of particular prosocial behaviors, either accelerating or delaying them, although the developmental pathways and mechanisms remain the same. Historically, the cognitive developmental approach to moral and prosocial development has framed it in terms of universal moral norms (e.g., respect for others) that originate in reason, and has argued against strong cultural relativism, which proposes moral thought and behavior unique to particular cultures. However, to the extent that these theories are constructvist, they clearly allow for individual differences. To some extent, the dichotomy between universality and relativism is also recreated in biological theories, albeit with common descent and heredity rather than reason as the framing point for universality.

Alternatively, culture can be seen as the medium in which all development, prosocial and otherwise, occurs (Rogoff, 2003). Cultural approaches may further invoke wholly separate cultural routes to prosocial development, involving different motivations and mechanisms by which children come to assist, comfort, and cooperate with others. For example, Kärtner et al. (2010) propose that German infants' prosociality develops out of a mentalistic self-other distinction, socialized by their mothers, whereas Indian infants additionally seem to display situational prosociality, which is oriented toward cooperative tasks and joint action as culture-specific characteristics. Arguably, this theoretical position can also be universalist in holding that human social functions, such as assisting others, develop universally, albeit through different pathways, i.e., individualistic versus collectivist norms (Greenfield et al., 2003). Of the major theoretical approaches to prosocial development, social learning theory is the most flexible in terms of examining and expecting broad cultural differences in prosociality.

Prosociality at Home

Rogoff's (2003) work on cultural development suggests that children get involved in different forms of prosocial behavior in the home environment across cultures. In some tribal cultures, such as the Efe in the Democratic Republic of Congo, even very young children are allowed to use machetes to cut fruit, whereas in typical North American households, kitchen knives, and sometimes even the kitchen itself, are considered off limits to young children, and only gradually sanctioned for use by older children. Thus, assisting others with meal preparation begins much earlier in the former. In many societies, children aged 5 and older begin to take care of other children, whereas in the UK, this is illegal if the older child is under 14.

In the urban United States, expectations for children's prosocial involvement at home appear substantially lower than for other societies and typically involve tasks such as cleaning up the house or one's bedroom and meal preparation (Klein et al., 2009). However, this cultural generality can vary from family to family. For example, children of single parents may be provided with more responsibilities to care for others and to take on more substantial household tasks (Rehberg and Richman, 1989). Conversely, families with paid domestic help demand substantially less prosocial behavior from their children (Klein et al., 2009). This suggests that social class,

although outside the purview of this article, is another important factor to consider in children's prosocial behavior.

Sharing

Rochat et al. (2009) examined sharing in children in five cultures (the US, China, Peru, Fiji, and Brazil), and sampled different social classes in Brazil. Children were asked to distribute candies and snacks between themselves and an experimenter over several trials. In one trial, children were asked to divvy up a 'perfect share' after which the experimenter would then decide the recipient. Across cultures, 3-year-old children were more likely to self-hoard (give all candies to oneself), but also to 'other-hoard' (giving all candies to the other), suggesting that young children may have had a different understanding of the task. In contrast, 5 year olds generally distributed candies more equally. At a cultural level, poor children from Recife in Brazil were the most likely to self-hoard, and Peruvian and Fijian children the most likely to other-hoard and also more likely to distribute fairly. US children were as likely to self-maximize their share of candy as some of the unschooled poor children.

Caring for Others

De Guzman et al. (2005), in a naturalistic study conducted in the rural Philippines and a small town in the United States, found that children in both settings were more likely to act prosocially toward infant relatives than toward child and adult relatives. However, children in the United States were more likely to act prosocially toward nonkin children, whereas children from the Philippines were more likely to help adult and infant relatives. The authors remark that their findings reflect in part vastly different social ecologies, particularly as older American children go to school, and thereby come into contact with far more same-age peers and are in infrequent contact with infants.

In an experimental study, Trommsdorff et al. (2007) found that when German, Israeli, Malaysian, and Indonesian children were playing with an adult whose balloon popped, it was the German and Israeli children who were the most likely to offer to comfort the adult. However, other-focused distress after the adult lost the balloon was high in all cultural groups. The experimenters hypothesized that in the Asian cultures face-saving may have been a factor in why the children did not offer comfort and care to the adult.

Modesty and Politeness

In research related to the concept of prosocial lying, Heyman et al. (2011) examined how children in Japan and America evaluated a child who committed a positive deed, either in public or in private. Japanese children evaluated truth-telling less positively than American children, and lying about one's good deeds less negatively, particularly when the question about the deed was asked in public. Ma et al. (2011) found similar patterns in Chinese children. Although both studies reflected children's judgments about a hypothetical situation rather than observed prosocial behavior, the researchers attribute this pattern of findings to a cultural norm of modesty in East Asian cultures.

Race and Ethnicity

In addition to class, race and ethnicity can contribute to subcultures within larger cultures. Spivak and Howes (2011) found that African-American children were slightly more likely to be prosocial than White or Latino children. Harris and Graham (2007) note that in some African-American neighborhoods values such as respect may emerge as prosocial, and that there may be fewer differences in prosocial behavior across racial and ethnic groups than within one's in-group.

Conclusions and Future Directions

From current studies of children's prosocial behavior, it seems clear that many prosocial behaviors occur at different rates across cultures, at least at an aggregate level. However, the data do not suggest that these cultural differences are absolute, such that some prosocial behavior in one culture is considered wholly wrong to members of another culture. It is also unclear how to group cultural differences in prosocial behavior, as there is often a great deal of variation even within supposedly similar societies (Rogoff, 2003). In the study by Heyman et al. (2011) and others, Asian cultures contrast with the US in terms of modesty. However, in the study of sharing by Rochat et al. (2009), Peruvian children seem more similar to children from Fiji than to children in neighboring Brazil, who behave more similarly to American children.

Although larger theoretical ideas about cultural influences underlie these findings, clearly a great deal more research needs to be conducted on prosocial behavior and development cross-culturally, including assessing children on multiple forms of prosocial behavior, before more decisive conclusions can be drawn, and this research must also consider social class, and race and ethnicity as part of the cultural fabric, particularly in heterogeneous societies.

In addition to longitudinal studies on prosocial development, current research on children's prosocial behavior, which is generally restricted to relatively discrete episodes, such as a child helping a parent or peer in distress, should also focus on children's longer-term prosocial commitments, which may emerge in new social and cultural contexts such as schools, community centers, and even the Internet.

Prosocial Behavior during Infancy and Early Childhood: Developmental Patterns and Cultural Variations

Jesse Drummond, Whitney E Waugh, Stuart I Hammond, and Celia A Brownell, University of Pittsburgh, Pittsburgh, PA, USA

Abstract

In their first years of life, infants exhibit a wide range of prosocial behaviors, including helping, sharing, comforting, and cooperating. Over the course of infancy, these behaviors become more sophisticated and socially appropriate. Although consistent age trends are demonstrated, prosocial behavior in infancy is best considered a multidimensional category consisting of distinct behaviors rather than a single unified construct. Moreover, the expression of prosocial behavior in infancy and its development are moderated by context, type of prosocial behavior, relationships with the others involved, and culture. Future research is needed to examine the effects of each of these factors on development and individual differences in early emerging prosocial behavior.

Prosocial Behavior in Infancy

Prosocial behavior in infancy is distinguished by great diversity and marked developmental change. The earliest manifestations of prosocial behaviors, traditionally defined as any intentional action that benefits another person (e.g., Grusec et al., 2002; Eisenberg et al., 2006), appear near the end of the first year of life (Hay and Cook, 2007), although some nascent forms of prosociality may appear earlier. These acts become progressively more coordinated, socially skilled, and often more frequent by the end of the third year (Hay and Cook, 2007) in concert with developing social, cognitive, language, and motor abilities (Moore, 2007).

Initial work on infants' prosociality focused on empathic responding, including both concerned attention and attempts to understand another's distress, and efforts to comfort the distressed other (e.g., Zahn-Waxler et al., 1979; Zahn-Waxler et al., 1992; Dunn, 1988; Rheingold, 1982; see Eisenberg et al., 2006 for a review). In the decades that followed these seminal works, researchers have uncovered a wide range of prosocial behaviors that infants exhibit in varied contexts and with different people (e.g., parents, siblings, peers, unfamiliar adults). Included on this spectrum are helping, sharing, cooperating, and comforting, as well as less prototypical behaviors such as informative pointing and participating in household chores. These behaviors are ubiquitous, often spontaneous, and enthusiastic.

In contrast to the broad picture of infant prosociality painted by this earlier research, recent investigations have explored its more fine-grained aspects and revealed some puzzling patterns. First, among toddlers, different prosocial behaviors are often uncorrelated with one another (Dunfield et al., 2011; Hay and Cook, 2007), suggesting that young children are not uniformly prosocial. Moreover, early prosocial behavior has been positively associated with aggression (Hay, 2006), and young children frequently ignore another's distress or exacerbate the victim's plight rather than exhibit concern or offer comfort (Dunn, 1988). These findings stand in stark contrast to the notion that prosocial behavior is a stable, early appearing, unified construct that governs much of early social interaction.

Knowledge of cultural variations in infant prosocial responding may contribute to our understanding of its development as well as its diversity. Although few in number, extant cross-cultural examinations of infant behavior reveal cultural differences in rates of prosocial responding in infants (Callaghan et al., 2011), how parents socialize prosociality in their infants (Mosier and Rogoff, 2003), and the mechanisms that motivate prosocial behavior (Kärtner et al., 2010).

In the following sections, we first describe the different types of prosocial behaviors children exhibit in infancy and how they change over the first few years of life. We then reflect on the developmental trends and multidimensionality of prosocial behavior. Finally, we consider cultural variations in early prosocial responding.

Describing Prosocial Behavior

In describing early developments in prosociality, we group behaviors into the three domains identified by Hay and Cook (2007): *feeling for others*, *ministering to others*, and *working and playing with others*. These domains, while not completely orthogonal, show some evidence of distinct patterns of internal coherence and provide a useful first step in understanding prosocial development.

Feeling for Others

The domain with the longest philosophical tradition, rooted in the theories of empathy and sympathy from thinkers such as Adam Smith, is feeling for others. Defined as "an affective response more appropriate to another's situation than one's own" (Hoffman, 2000: p. 4), empathy has long been considered a potent motivator of prosocial behavior and a necessary component of prosocial development in adults and children alike (Batson, 1991; Eisenberg et al., 2006). According to Hoffman, an infant's ability to empathize with another first manifests in reactive contagious crying in the first few days of life and gradually develops into veridical empathic concern in the third year. At this latter age, a child can empathize with another in distress, take another's perspective, and reflect on

others' needs. Although the demonstration of empathic concern for another in distress has itself been considered a prosocial response, the process of empathizing with another may act as a mechanism for all kinds of prosocial behaviors (Davis, 2005).

Empathic concern is traditionally operationalized as facial and/or vocal expressions of concern, including sad or worried looks (e.g., plaintive face with furrowed brow and downturned mouth) and sympathetic statements (e.g., "I'm sorry") (Zahn-Waxler et al., 1992). In a longitudinal examination of infants' empathic concern in response to naturally occurring and simulated distresses in the home, Zahn-Waxler and colleagues found that infants aged 13–15 months showed very low levels of empathic concern, whether they had caused the distress or not; by 23–25 months, infants were showing empathic concern significantly more frequently. This pattern of findings suggests that infants are capable of feeling for another at the beginning of their second year, although they rarely act on this ability. Their propensity to empathize with another, or at least their demonstration of this propensity, grows significantly with age.

Recent work has experimentally examined situational differences in children's empathic responding. Spinrad and Stifter (2006) examined 18-month olds' concerned attention to their mother, a stranger, and a crying baby doll. Infants showed more concerned attention toward the baby than toward the stranger or the mother, and more concerned attention toward the stranger than toward the mother. Nichols et al. (2009) showed similar situational differences: infants between 12 and 24 months of age showed significantly more empathic concern to a crying baby than to their mother.

In sum, feeling for others, measured by empathic concern in response to others' distress, is evident early in the second year and becomes more prevalent as children reach the third year. Infants exhibit empathic concern toward many different others, while also showing situational specificity in their empathic responding. Somewhat paradoxically, however, the ability to feel for others may also result in personal distress in response to another's distress, which is quite prevalent in young infants and may inhibit some of the more overt prosocial behaviors described below (Eisenberg et al., 2006).

Ministering to Others

In the second year, infants respond to the needs of others in specific goal-directed and instrumental ways that reveal some level of understanding of the other's current situation and need (Hay and Cook, 2007). This domain of actions, referred to as ministering to others, includes comforting, nurturing, and helping.

Infants show a remarkable ability to comfort others in distress, even at very young ages. They will hug distressed victims, bring them objects to soothe their distress, find someone else to help them, or give them physical assistance (Dunn, 1988; Vaish et al., 2009; Zahn-Waxler et al., 1979). In concert with developments in empathic concern, comforting behaviors grow in frequency and complexity over the second and third years. At the beginning of their second year, infants tend to comfort others infrequently and use predominantly physical means (e.g., hugging or patting; Zahn-Waxler et al., 1992). At this age they also tend to inappropriately overgeneralize specific actions to new and different situations; for example, a child who pats his mother on the head after she has hit it on a cabinet and then does the same to a sibling who has fallen and scraped his knee (Dunn, 1988). In their third year, toddlers comfort distressed others more frequently and do so in more elaborate ways, including using distraction or humor and protecting the other from further harm (Zahn-Waxler et al., 1992; Dunn, 1988). Toddlers at this age also tend to persist in their comforting efforts, trying a number of different comforting techniques (Dunn, 1988). Importantly, they also begin to respond to conditions of need even in the absence of overt emotional distress (Dunn, 1988; Vaish et al., 2009).

Many of the comforting behaviors captured in these studies occurred in response to a younger sibling in distress (Dunn, 1988). This finding, when coupled with those described above with respect to concerned attention to a crying baby, suggests that infants in their second year are able, and at times willing, to nurture others. Although it has been documented in many different societies (Hay and Cook, 2007), nurturing as an early form of prosocial responding has yet to be studied directly.

Infants also show a propensity to help others. An early form of helping involves completing goal-directed actions to remedy another's specific problem (e.g., fetching an out-of-reach object that an adult needs to finish a task). This 'instrumental helping' behavior emerges just after the first birthday at about 14 months of age, consistent with an infant's developing ability to understanding and act upon an adult's desire or need (Warneken and Tomasello, 2007; Svetlova et al., 2010). By midway through their second year, infants show similar goal-directed helping in more difficult tasks, such as opening a cabinet for an adult who is holding several heavy books or helping him stack objects (Warneken and Tomasello, 2006). Moving into the third year, infants show an increasing propensity to help in these goal-directed ways. When given the opportunity to fetch out-of-reach objects, 24- (Dunfield et al., 2011) and 30-month-old infants (Svetlova et al., 2010) help significantly more frequently than 18-month-olds. Indeed, in a recent analysis of helping behavior in infancy, almost all 30-month-old infants helped on every occasion while less than half the 18-month-old infants did so, illustrating the growing ability to understand and alleviate another's need (Svetlova et al., 2010).

However, infants find more complex helping scenarios challenging. When an adult needs an object to alleviate a more abstract emotional need (e.g., a toy to make him happy after he begins to cry), infants up to 30 months of age help significantly less frequently than they do when the adult needs an object to complete a concrete goal-directed action (e.g., a clothespin to clip a cloth to a clothesline); their performance decreases still more when it is the infant's own toy that would alleviate the adult's emotional need (Svetlova et al., 2010). Nevertheless, 30-month-old infants show a much greater ability to help a sad adult by bringing him a toy than do their 18-month-old counterparts (Svetlova et al., 2010), illustrating their greater perspective-taking ability and emotion understanding.

In sum, early in their second year, infants begin to comfort and help others in distress. This ministering behavior becomes

more frequent, varied, and appropriate over time. By the end of the third year of life, infants can quite readily grasp the needs of another in distress, whether action-based or emotional, and aid in addressing those needs.

Working and Playing with Others

In addition to feeling for and ministering to others, infants also begin to work and play cooperatively with others. They explore their social world, participating in and often facilitating social interaction with others. Beginning in the second year of life, they spontaneously cooperate in joint actions, help others with chores, and share what they have and what they know with those around them (Brownell, 2011; Hay and Cook, 2007).

In everyday interactions with siblings, peers, and parents, infants are spontaneous and enthusiastic cooperators. Infants will eagerly fetch a car that has run off the track so her sibling can run it down the track again, or bring her sibling more puppets to play with if he is putting on a puppet show (Dunn, 1988). These actions are often unprompted and coupled with positive affect and joy (Dunn, 1988). Such cooperative exchanges have been reported in infants as young as 12 months, when they mostly consist of showing and handing interesting objects to parents (Hay, 1979); by 14 months some infants will reengage an adult who has interrupted a joint activity, illustrating their enjoyment of joint participation and possibly demonstrating rudimentary understanding of cooperation toward a joint goal (Warneken and Tomasello, 2007). As children develop through the second and into the third year, these cooperative interactions become more frequent and more explicitly coordinated (Dunn and Munn, 1986; Dunn, 1988; Warneken et al., 2006; Brownell et al., 2006).

Beginning in the second year, infants also begin to participate with their parents in routine household tasks. In a seminal study, Rheingold (1982) found that most infants between 18 and 30 months of age eagerly began to participate together with their parents, and in some circumstances an unknown adult, in a series of household tasks designed to resemble chores that parents do around the house (e.g., sweeping, setting the table). Toddlers often began to participate as soon as the parent stated her intent and did so with enthusiasm and positive affect. They frequently coupled their actions with vocalizations reflecting an understanding of the goal, such as those stating an intention (e.g., 'I can do messy papers') and signaling completion (e.g., 'all clean') (Rheingold, 1982: p. 119). The frequency of these behaviors and vocalizations increased with age, and by 30 months many of the infants spontaneously used the word 'help' to describe their participation. While the intention to help is clear, proficiency is another matter; parents report that their child's participation is often unhelpful or even counterproductive, and some parents will refrain from doing chores until their child is asleep.

In addition to participating in these joint activities with others, infants begin to share with others during the second year. This is first evident in infants' informative pointing, which emerges around the first birthday or soon thereafter. For example, they share information they themselves have about the location of an object that another has lost and is seeking (Lizkowski et al., 2008). In the middle of the second year, infants begin to share tangible resources such as toys or food with others. These early sharing behaviors require considerable communicative support about the potential recipient's need, and young infants often share only after a direct request, but with age they share more quickly (Brownell et al., 2013; Dunfield et al., 2011). Interestingly, other analyses of sharing behavior have found that the frequency of sharing may level off or even decrease over the preschool years as children become more selective in choosing when and with whom to share (Hay and Cook, 2007).

In sum, starting around their first birthday, infants begin to cooperate with others, participate with others in everyday tasks, and share both information and material resources with others. These prosocial behaviors gradually become more spontaneous, frequent, and sophisticated over the course of infancy, preparing infants to enter childhood armed with a considerable array of prosocial skills and grounding the further development of social competence over childhood and adolescence.

Multidimensionality of Prosocial Behavior

Despite general patterns of growth common to feeling for others, ministering to others, and working and playing with others, prosocial behavior is not a single unified construct, nor is it motivated by the same underlying altruistic tendencies; indeed, different prosocial behaviors have distinct correlates (Dunfield et al., 2011), and evidence for relationships among different forms of prosocial behavior is mixed. Goal-directed helping in the second year is generally unrelated to other forms of prosocial behavior, such as sharing (Dunfield et al., 2011) and cooperating (Warneken and Tomasello, 2007). Concerned attention to another in distress is significantly related to prosocial interventions in some situations, but not in others (Zahn-Waxler et al., 1992; Spinrad and Stifter, 2006). Similarly, certain prosocial behaviors show consistency across some contexts, but not others (Nichols et al., 2009; Spinrad and Stifter, 2006). Recent findings have also revealed distinct neurocognitive mechanisms for different prosocial behaviors: Paulus et al. (2013) found that instrumental helping was associated with greater right than left cortical temporal activity, while comforting was associated with greater left than right frontal activity.

In addition, prosocial behavior is often exhibited concurrently with antagonistic behaviors. In the first year, sharing is positively correlated with aggression (Hay, 2006; Hay and Cook, 2007). Children at this age can be simultaneously comforting and violent, as in the case of a young girl who upon seeing a friend cry after his ball was taken by another child, bit the child who took the ball and returned it to her friend (Dunn, 1988). The victim in distress is not immune from these inconsistencies, as illustrated by a 30-month-old who patted his crying brother, tried to distract him, spoke affectionately to him, and, when all bids failed, threatened to hit him if he did not stop crying (Dunn, 1988). Prosocial behavior also occurs at fairly low rates, and children quite routinely respond to distress by ignoring the victim, laughing at the victim, or even exacerbating the victim's distress (Hay and Cook, 2007; Dunn, 1988).

Prosocial behavior, then, is best understood as a multidimensional construct consisting of distinct behaviors that vary

across different situations and that may be governed by distinct mechanisms. As a corollary, the findings suggest that the same behavior may be driven by different mechanisms for different infants (Kärtner et al., 2010): for one child, the ability or propensity to empathize with an adult's perceived distress may motivate his retrieving of a dropped object; for another, a strong desire to affiliate with others may be the driver. Complicating matters is that these motivations are not mutually exclusive and may operate simultaneously within any one child.

So how do we make sense of prosocial behavior in infancy? The first step may be to acknowledge that what unifies these behaviors is their social orientation. As described by Hay and Cook (2007), "early prosocial tendencies may best be seen as a basic impulse to engage positively with other people that only gradually becomes *selective*, *socially appropriate*, *self-regulated*, and *morally informed* activity" (original emphasis) (p. 102). Future work is needed to establish coherent patterns among these different behaviors at different ages and to examine how this gradual change occurs.

Cultural Variation in Prosocial Responding

There has been relatively little research devoted to cultural differences in prosocial behavior across infancy and early childhood, in part due to prevailing theory that early prosocial behavior is universal and evolutionarily selected, and thus culturally invariant (e.g., Warneken and Tomasello, 2006). Consistent with this view is the assertion that prosocial behavior only becomes rule-governed as children leave the infancy period, suggesting that cultural norms only exert their influence later in development as older children become more directly engaged in cultural institutions (Hay and Cook, 2007).

Still, there is reason to believe that early prosocial behavior may vary by culture. For example, Canadian and Peruvian infants, aged 10–13 months, direct an adult's attention toward interesting stimuli more frequently than age-matched Indian infants; 2-year-old infants in Canada exhibit higher rates of instrumental goal-based helping with adults than do infants in India and Peru; and infants in India and Peru collaborate more frequently with an adult than do infants in Canada (Callaghan et al., 2011).

Parenting styles in both play and disciplinary contexts may influence the transmission of prosocial behavior and values beginning in infancy (Hay and Cook, 2007; Pettygrove et al., 2013). Empathic caregiving, for example, has been associated with prosocial responses to distress in the second year (Zahn-Waxler et al., 1979) and certain parenting techniques (e.g., guilt induction) are considered crucial for early prosocial and empathic development (Hoffman, 2000). An infant's sense of responsibility and agency in moments of distress may be reduced by frequent parent interventions (Hay and Cook, 2007). These findings become culturally relevant when we consider that parenting styles, values, and techniques vary dramatically by culture.

The consequences of parenting style for prosocial development in distinct cultures are illustrated by the work of Mosier and Rogoff (2003) with American and Guatemalan families. When conflict arose between infants in their second year and their older siblings, Guatemalan mothers tended to bestow a privileged status upon their infants, allowing them to do whatever they pleased; in contrast, American mothers expected their infants to abide by the same rules as their older siblings. Guatemalan mothers rarely, if ever, forced their infant to cooperate, instead attempting to persuade and ultimately acquiescing to the infant's desire. This privileged status of Guatemalan infants was also endorsed by their older siblings, aged 3 and 5 years, even when the mother was absent. Accordingly, more infant–sibling interactions among Guatemalan children included offering objects, helping others with objects, and jointly working with objects, whereas more infant–sibling interactions among American children included conflict over objects.

Mirroring this finding in other cultures, Kärtner et al. (2010) found that parents in Delhi, India, rated obedience-related socialization goals (e.g., learning to obey parents and older people) as more important than did parents from Berlin, Germany. The proportions of children showing prosocial and tentative prosocial responses varied marginally between cultures, but in both cultures the degree to which parents emphasized obedience-related socialization goals was associated with their infant's prosocial responses to distress. In addition, Kärtner et al. (2010) found that mirror self-recognition, a measure of self-other differentiation, was related to prosocial behavior only in the Berlin sample. That infants in Delhi responded prosocially whether or not they possessed a theoretically important socio-cognitive prerequisite illustrates that different developmental pathways, some emotion-based and others action-based, may exist for the same behaviors (Kärtner et al., 2010; also see Svetlova et al., 2010). Thus, mechanisms of prosocial development apart from parenting may also vary by culture.

Conclusions and Future Directions

In their first few years, infants develop a remarkable capacity for acting in myriad ways to benefit others. These behaviors are often unrelated to one another and show relatively little consistency across different types of tasks. Further, the expression of prosocial behavior in infancy, and its development over time, is moderated by context, type of prosocial behavior, relationships with the others involved, and culture. While the motivations for prosocial behavior in such young children are still largely unknown, and may be multiple and overlapping, the role of social interaction in its development and expression is unquestionable (Hay and Cook, 2007).

Research findings imply that prosocial behavior is multidimensional and includes different elements that may be qualitatively distinct. The influences of corollary factors on prosocial development in infancy and early childhood, when prosocial behaviors are first emerging, warrant further examination. The role of culture is especially elusive given the relative paucity of investigations of cultural differences in early prosocial responding, but the recent finding of culturally variant pathways to prosocial development (Kärtner et al., 2010), offers a promising new perspective on the contributors to developmental change.

Abstract

Humans frequently act in ways that benefit others or contribute to their society. Despite this common human capacity for prosocial behavior, populations can differ dramatically in the propensity to engage in various kinds of helping, sharing, and cooperation. In this article, we review empirical findings of cross-population diversity in prosocial behavior, outline current theories for these population differences, and identify future areas for research.

Introduction

The odds of a stranger coming to your aid on the street depend in important ways on the location of that street. In one international study, residents of Rio de Janeiro and Lilongwe (Malawi) nearly always helped strangers – assisting blind people at a street corner, alerting strangers to dropped pens, and helping handicapped pedestrians gather their dropped belongings (86–93% of the time). Meanwhile, residents of New York City and Kuala Lampur helped strangers in these same tasks less than half the time (40–45%) (Levine et al., 2001). Researchers have observed comparable cross-population variation in other prosocial behaviors, including how people voluntarily share a pot of money with an anonymous other (Henrich et al., 2005, 2010a), contribute to a public good (Buchan et al., 2009; Herrmann et al., 2008; Fearon et al., 2009), punish norm violators (Henrich et al., 2006), follow an impartial rule, and help a friend in the face of countervailing social norms (Trompenaars and Hampden-Turner, 1997). In many cases, educated members of western industrialized countries are at the far end of the human spectrum (Henrich et al., 2010b).

Scholars have formulated a number of potential explanations for cross-population variation in prosocial behavior, including population size and density, market integration, religious affiliation, connection with the global community, quality of institutions, and pathogen stress. In this article, we review the existing evidence from psychology, anthropology, and economics for cross-population variation in how people engage in prosocial behavior. We then outline prominent hypotheses for these differences, as well as recent attempts to test these hypotheses.

Operationalizing Prosocial Behavior for Cross-Population Studies

Intuitively, prosocial behavior can include donating money to charity, volunteering time at a soup kitchen, helping a friend with homework, following rules of good behavior, protecting the weak, and keeping the peace. Psychology has a rich tradition of studying prosocial behavior, and researchers have proposed a diverse set of definitions for the concept (Batson and Powell, 2003; Eisenberg et al., 2007; Penner et al., 2006). Most definitions concur that a prosocial act benefits others, but they differ in more fine-grained requirements about intention, motivation, and the cost to the actor. Was the benefit intended? Was the behavior voluntary or intrinsically motivated? Did the actor incur a cost? Here, we consider prosocial behavior in its broadest sense – acts that benefit others – understanding that it may be important to consider these more fine-grained questions when studying any specific behavior.

Within this broad set of behaviors, Batson also outlines three major classes: (1) aiding another person, (2) contributing to a group, and (3) following a socially valued rule, such as being honest or respecting another's property (Batson and Powell, 2003). Researchers have used several methods for assessing and comparing these different kinds of prosocial behaviors across populations, including asking people how they would respond in hypothetical scenarios (Trompenaars and Hampden-Turner, 1997; Gelfand et al., 2011), examining allocations of real money and other goods in behavioral experiments (Henrich et al., 2005, 2010a; Buchan et al., 2009; Herrmann et al., 2008; Rustagi et al., 2010), and observing how people help when confronted with experimenter-created situations in the real world (Levine et al., 2001). In this article, we focus primarily on studies of real rather than hypothetical behavior, which are currently limited to a few kinds of prosocial acts: (1) helping a stranger (Levine et al., 2001), (2) sharing a pot of money or goods with an anonymous stranger (Henrich et al., 2005, 2010a), (3) sacrificing to punish a cheater (Henrich et al., 2010a, 2006), (4) contributing to a public good (Herrmann et al., 2008; Rustagi et al., 2010; Buchan et al., 2009), (5) following an explicit rule for allocating goods (Hruschka et al., 2014), and (6) reciprocating a transfer of goods (Vollan, 2012).

The Scale of Cross-Population Variation

Population differences in prosocial behavior emerge at many scales – between communities from different countries (Levine et al., 2001; Herrmann et al., 2008), between urban and rural populations in a country (Steblay, 1987), between cities within countries (Levine et al., 1994), between communities from different small-scale societies (Henrich et al., 2005,

 http://dx.doi.org/10.1016/B978-0-08-097086-8.24103-2

2010a), and between communities from the same ethno-linguistic group (Henrich et al., 2005, 2010a; Lamba and Mace, 2011; Rustagi et al., 2010; Vollan, 2012; Fearon et al., 2009). Researchers frequently refer to variation between ethno-linguistic groups or between countries as 'cross-cultural,' a habit which implies that such variation is due to variation in culture – socially learned modes of thought and behavior. However, it is entirely possible that such cross-population differences result instead from common responses to a shared ecological or social environment or even to genetic differences (Eisenberg and Hayes, 2011; Chiao and Blizinsky, 2010). Conversely, variation within ethno-linguistic units has been inferred to result from environmental or ecological factors since culture must be constant within such groups (Lamba and Mace, 2011). This too is a premature inference (Henrich et al., 2012), since communities within the same ethno-linguistic unit can also differ in terms of socially learned modes of thought and behavior. Modern evolutionary approaches to 'culture' have long dispensed with essentializing notions that attribute 'cultures' to entire ethno-linguistic groups. For these reasons, we describe observed differences simply as 'cross-population differences' until the underlying causes and mechanisms are identified (following Henrich et al., 2010b).

Explanations for Cross-Population Variation in Prosocial Behavior

Many explanations for population variation in prosocial behavior hinge on differences in values, such as collectivism, embeddedness, or self-expression, which are hypothesized to motivate helping and sharing in different ways (Knafo et al., 2009; Levine et al., 2001). For example, some cross-cultural psychologists have proposed that individuals in societies with greater collectivism will be more generous to in-group members but either equally or less generous to out-group members (Triandis, 1989). Others have argued that region-specific values, such as *simpatico* in Spanish and Latin American cultures may account for population differences in helping (Levine et al., 2001).

Value-based arguments outline a link between cognition and behavior, but they leave open the question of how these value differences arise. One possibility is that these values simply reflect particular cultural histories of different populations. According to this argument, over the course of human history, some groups became more collectivist and others more individualist in an arbitrary process of cultural drift. Another possibility is that prosocial values and behaviors respond to or coevolve with specific social and material situations in predictable ways. Here we review seven prominent explanations which propose general processes of coadaptation with the environment.

Before reviewing these explanations, it is important to consider a key difference in how they view behavior interacting with the environment. Some theories treat the physical and social environment as an exogenous driver of behavior (e.g., greater population density leads to less helping of strangers or greater pathogen stress leads to increased favoritism toward in-group members). Other theories posit that physical and social environments can themselves arise from patterns of prosocial behavior. For example, infectious disease risk, which is proposed by some theories to be a driver of prosocial behavior, is not simply an exogenous element of the environment. Rather it has changed in response to the emergence of public health institutions, which were in turn the outcome of early prosocial attempts to improve others' health. Such feedback between environments and behavior can lead to significant coevolutionary trajectories. According to some theories, these trajectories may account for the modern-day emergence and maintenance of cultural systems such as markets and world religions (see following section). If such feedbacks exist, it is also possible that the processes described in the following section may interact in important ways, rather than being independent and mutually exclusive explanations.

Population Density and Size

A number of theories predict that population size or density influence prosocial behavior. Milgrim argued that living in cities had a number of cognitive consequences, including a reduction in prosocial behavior toward strangers. Specifically, with increasing population density and frequency of interactions among strangers, individuals cannot plausibly concern themselves with everyone they meet. Rather, they develop norms whereby they selectively attend to known individuals, but effectively ignore strangers. According to this hypothesis, as people interact more frequently with a larger number of individuals, we would expect them to become less helpful toward strangers (Milgrim, 1970). Darley and Latane propose an alternative hypothesis that individuals are less likely to offer help when more potential helpers are present at the immediate location as this makes any single person less responsible for helping. This explanation based on a bystander effect predicts that individuals will be less helpful when more people are around (Latane and Nida, 1981; Darley and Latane, 1968). A third line of reasoning from economics and sociology focuses on the size of communities, rather than population density. It predicts that individuals will be less willing to help, share, or engage in collective action in the context of larger communities, because it is more difficult to enforce the eventual return of that prosocial behavior (Olson, 1965). A fourth argument proposes instead that larger communities cannot function without indoctrinating members with internalized norms of generalized sharing, helping, and cooperation. This indoctrination among larger groups might counteract or even reverse the effect of strategic decisions to defect and might even increase levels of prosociality in larger communities (Henrich et al., 2010a). Consistent with the first two explanations, a study of helping behavior in 36 US cities found that increasing population density (rather than size) was the strongest predictor of decreasing willingness to help strangers in a number of situations (Levine et al. 2001). In other studies of sharing and contributions to collective efforts, community or group size has shown mixed results (Henrich et al., 2010a; Lamba and Mace, 2011; Henrich et al., 2012). Indeed, consistent with the fourth argument, a recent multisite study showed that one kind of prosocial behavior, anonymous prosocial punishment, actually *increased* with increasing community size (Henrich et al., 2010a).

Market Integration

The market integration hypothesis proposes that market norms emphasizing fair treatment of anonymous others have culturally evolved to sustain mutually beneficial exchanges in contexts demanding frequent interaction with strangers. In turn, as individuals increasingly interact with markets, they adopt and internalize these norms (Henrich et al., 2010a). Reciprocally, markets spread more successfully in places with such norms. According to this hypothesis, individuals with greater market exposure will be more likely to have adopted or internalized these norms and thus will treat anonymous others more fairly. This hypothesis has been tested, replicated, and extended in two separate projects covering 24 different societies scattered across the globe, from Siberia to New Guinea. The populations involved hunter-gatherers, slash-and-burn horticulturalists, subsistence farmers, and wage workers. Overall, more market integrated societies tend to make more even splits of a pot of money, independent of the threat of punishment, income, wealth, education, community size, sex, and age (Henrich et al., 2005, 2010a). Since such equitable tendencies emerge even when punishment is not possible, and anonymity is assured, the authors argue they arise from internalized local norms. Supporting the internalization hypothesis, recent work shows that 'giving' by westerners in such experiments is the automatic response (Rand et al., 2012) and involves activation of the brain's reward circuitry (Harbaugh et al., 2007).

Two important concerns with Henrich et al.'s projects revolve around the many sources of variation in such a large, global sample (many factors probably are not controlled for), and the direction of causality – market integration in these studies – cannot be identified as an exogenous cause. Both concerns have been addressed recently. Among 57 communities in a single ethno-linguistic herding group in Ethiopia, Rustagi et al. (2010) measured people's willingness to cooperate with strangers in an economic game. Since these groups are tied to their land by customary rights, people's distance to markets can be used as a proxy for market integration that is exogenous (not subject to reverse causality). Herders who live closer to markets were more cooperative, even after statistically controlling for sex, wealth, literacy, land, and many other variables. Here market contact seems to have caused people to be more cooperative in anonymous situations. Perhaps most importantly, groups with more cooperators were better able to make, monitor, and enforce local agreements that resulted in measurable improvements in forest conservation (Rustagi et al., 2010). That is, the experience of markets changes our sociality to make it easier to construct and enforce certain kinds of institutions – increasing institutional quality. Voors et al. (2012) have similar findings from Burundi.

Religion

Many religious traditions emphasize the importance of prosocial behavior, and thus enculturation in specific religions may influence prosocial behavior. Numerous studies in psychology have now shown that 'priming' (unconsciously bringing to mind) thoughts of god causes theists, but not atheists, to give more in behavioral games (Norenzayan and Shariff, 2008). One current theory holds that modern world religions, such as Christianity and Islam, were able to spread precisely because they effectively enculturated norms of prosocial behavior which galvanized large-scale cooperation among relatively anonymous strangers (Atran and Henrich, 2010). According to this view, followers of modern world religions, such as Christianity and Islam, will be more likely to have internalized these norms of prosocial behavior and will thus treat anonymous others with greater fairness and generosity. Findings from the cross-society studies described earlier are also consistent with this hypothesis (Henrich et al., 2010a).

Institutional Quality Hypothesis

Variants of the institutional quality hypothesis propose that informal and formal institutions change the costs and benefits of prosocial behavior, which in turn shape the social norms and behavior. Public services, global markets, and social safety nets that mitigate material threats may render investments in an expansive network of kith and kin less necessary as alternative forms of social insurance (Inglehart and Welzel, 2005; Hruschka, 2010). Legal mechanisms guaranteeing relatively safe exchange and interaction in largely anonymous settings lower the costs of interacting with and cultivating beneficial relationships with strangers. Finally, to fully participate in these institutions, individuals must follow norms of fairness and civil interaction (Hruschka and Henrich, 2013). Based on this hypothesis, when individuals have access to functioning formal institutions, they are more likely to follow institutional rules, such as honest communication and equitable treatment of others. Moreover, reduced barriers to and increased benefits of cultivating beneficial relationships with strangers will lead to greater trust with anonymous individuals and reduced parochialism in prosocial behavior. This hypothesis is consistent with a recent study comparing trusting behavior among Nama pastoralists across two countries varying in institutional quality (Namibia and South Africa) (Vollan, 2012). It is also consistent with findings from an international study of rule following and parochialism across eight sites which varied in terms of institutional quality (Hruschka et al., 2014).

Globalization

This explanation proposes that as people increasingly participate in the network of global, social, and cultural relations, they are less likely to think in terms of in-groups and out-groups and more likely to imagine humankind as a 'we' where there are no 'outsiders' (Buchan et al., 2009). Thus, individuals with greater interactions with global communication (e.g., cell phones, televisions, and employment in transnational firms) will be more inclined to engage in collective action with individuals outside of their immediate in-group. Consistent with this hypothesis, Buchan et al. (2009) found that contribution to global public goods increases when people identify with the world rather than their own nation.

Pathogen Stress

Recently, several evolutionary researchers have proposed that preferential prosociality toward in-group members constitutes a form of behavioral immune system against the spread of pathogens. According to this hypothesis, in regions with high risk of infection by dangerous pathogens, individuals will preferentially interact with in-group members in a way that insulates them from infection by out-group members (Fincher and Thornhill, 2012; Schaller and Murray, 2010). Although originally predicting xenophobia (negative out-group attitudes and behaviors), the theory has been extended to account for in-group favoritism (positive in-group attitudes and behaviors) as well (Fincher and Thornhill, 2012). This hypothesis differs crucially from other hypotheses by positing that the adaptive mechanisms responsible for this effect are specific to pathogen risk and were designed to impede the spread of pathogens. Emerging experimental evidence suggests that people do indeed adjust social motivations and behaviors (i.e., conformism) to specific cues of pathogen threats over and above generalized threats (Murray and Schaller, 2012). However, existing cross-population analyses suggest that broad population variation in prosociality is more likely a result of other factors, such as institutional quality or extrinsic risk (Hackman and Hruschka, 2013, Hruschka and Henrich, 2013).

Experience of War

Evolutionary researchers have also proposed that humans should be sensitive to the threat or experience of intergroup conflict. Work with senior Israeli citizens before, during, and after the 2008 conflict with Hezbollah (Gneezy and Fessler, 2012), shows that people's willingness to punish unfairness increased during the war, but returns to prewar level soon after. Consistent with this, research in both the Republic of Georgia (Caucuses) and Sierra Leone (West Africa) converges to indicate that the experience of war during a developmental window from roughly age 7 to 20 increases people's 'parochial egalitarianism' – their tendency to favor more equal sharing within their in-group, relative to an out-group (that is not the opponent). This effect endures at least a decade post conflict (Bauer et al., 2012). Convergent lines of experimental research have emerged from conflict studies in Burundi (Voors et al., 2012). Since different populations have different recent experiences of war, we should expect global variation to arise from this factor.

Future Directions – Prosocial Trade-Offs and Social Norms

In addition to identifying population variation in behavior, cross-population studies can lead to better theory and research by productively challenging common assumptions about prosocial behavior. Consider the case of raiding parties among East African Turkana pastoralists. On occasion, Turkana males assemble large war parties, raid neighboring ethnic groups, and steal their victims' herds. Despite the high potential costs of participating in a raid, many warriors resist the urge to desert their party, and instead assist in the theft. If instead a warrior chooses to shirk and desert his companions, he faces a number of potential consequences. Community members may verbally rebuke him or they may demand that he sacrifices an animal from his herd. In especially egregious cases, the deserter's age-mates may tie him to a tree and beat him with a whip (Mathew and Boyd, 2011). Participating in cattle theft and exacting retributive justice are not actions that most readers would associate with prosociality. Yet these acts – assisting one's comrades and punishing a cheater – are intended to benefit others and to contribute to the well-being of one's group, two key criteria of prosocial behavior (Mathew and Boyd, 2011).

The Turkana example illustrates two important points. First, any given social situation can invoke many potentially contradictory prosocial motives – helping companions, protecting one's community and its territory, or respecting the life, property, and happiness of others. In this thicket of competing motives and outcomes, humans can disagree, sometimes dramatically, about what motives, behaviors, and outcomes are most desirable and thus what counts as prosocial or antisocial. Even an act as apparently prosocial as excess generosity can be considered antisocial if it comes off as flaunting one's advantage, as an attempt to bring another person into one's debt, or simply as violating a norm of moderation (Herrmann et al., 2008). To address this ambiguity, social norms often emerge in frequently encountered contexts to establish the appropriate way to behave. Even within a single society, different contexts can call for different behaviors. In the USA, helping a friend is good, but helping a friend make money on the stock market by leaking company secrets is not. Among Samburu pastoralists of north-central Kenya, individuals are more likely to evenly split a pot of money if the activity is framed in terms of traditional meat sharing than as a decontextualized sharing game (Lesorogol, 2007). Work examining population and contextual variation in what counts as the appropriate or prosocial way to act in specific contexts will shed important light on how social norms of prosociality are formed and how they guide behavior.

Second, humans live in complex webs of social relationships with frequently conflicting allegiances and obligations. Sacrificing for one person or group may mean injuring or neglecting another (Reicher et al., 2012). Thus, while the willingness to sacrifice for others or for one's group appears to be a recurring aspect of human psychology, human populations differ markedly in the allegiances and obligations seen as most important and in the behaviors most appropriate when acting in the service of others, one's group, or on a moral principle. Consider a pedestrian who walks past an injured bicyclist without offering aid. Perhaps that pedestrian is being selfish with her time. Or, perhaps she is trying to catch a bus to comfort her friend in the hospital. Alternatively, consider allocations in the dictator game, where an individual can divide $10 between himself and an anonymous stranger. The money kept for self is usually considered the selfish option. However, if the person turns around and spends that money on food to be shared with others, the 'selfish' decision simply reflects a different preference for prosocial sharing. These prosocial outside options can be difficult to control and measure in scientific studies. However, given potential cross-population

differences in such outside options, they should be carefully considered when interpreting cross-population variation in observed behavior. More generally, by clearly specifying alternative prosocial options, researchers can gain insight into how people make tough decisions between apparently incommensurate kinds of 'good' behavior.

A key problem in understanding both how prosocial norms arise and how people negotiate prosocial trade-offs is to understand the time scales of change that give rise to cross-population variation (Schaller and Murray, 2010). On very short time scales, people likely have some ability to make facultative calculations about the relative merits of investing in different prosocial options, as we saw when individuals punished more during a war. On developmental timescales, early life experience may influence one's willingness to engage in certain kinds of prosocial behavior toward others, as we see in Sierra Leone and Georgia (Bauer et al., 2012). On generational timescales, people acquire culturally transmitted beliefs, norms, motivation, habits, practices, values, reasoning styles, or strategies by using adaptive learning heuristics. Cultural traits that permit individuals or groups to successfully manage beneficial social interactions can spread and persist through a variety of cultural evolutionary processes (Henrich et al., 2010a). At the deepest timescale, if cultural niches are sufficiently stable, natural selection may favor genes that foster different amounts of in-group investment (Chiao and Blizinsky, 2010; Eisenberg and Hayes, 2011). Integrating study designs across these various timescales – including behavioral and field experiments and longitudinal and cross-population analyses – will be crucial for identifying how these population differences in prosocial behavior arise and persist (Hackman and Hruschka, in press).

Prosocial Behavior, Effects of Parenting and Family Structure on

Liat Hasenfratz and Ariel Knafo, The Hebrew University of Jerusalem, Jerusalem, Israel

© 2015 Elsevier Ltd. All rights reserved.

Abstract

It is widely acknowledged that parents from different cultural communities use different techniques to socialize prosocial behaviors and these differences are associated with differences in quantity and quality of prosocial behaviors. There is, however, a wide disagreement regarding the exact role that culture has in explaining observable phenomenological differences and thus relatively little systematic research on parenting and the development of prosocial behavior in a cross-cultural context. The authors, thus, use individual existing studies to create an overview of the cultural variety in parenting and prosocial behavior and to outline how culture, parenting and prosocial behavior interact in concert to create diversity in forms of human cooperation and compassion.

Introduction

This article aims to contribute to an understanding on the relationship between parenting and children's prosocial behavior from a culturally informed point of view.

The socialization of prosocial behavior has been studied almost entirely among Western white middle class populations. Theories on the socialization of prosocial behavior have largely been developed by researchers in North America (e.g., Grusec and Goodnow, 1994; Hoffman, 1988). In contrast to the well-researched relationship between parenting and prosocial behavior, there is very little research on parenting and prosocial behavior in a cross-cultural context.

Across the world, the particular ways by which parents interact with their children is influenced by the particular cultural beliefs about the human nature and its development, and beliefs about the role of parents in promoting adaptive social development (i.e., parental ethnotheories, Harkness and Super, 2006). It is widely acknowledged that parents from different cultural communities use different techniques to socialize prosocial behaviors and these differences are associated with differences in quantity and quality of prosocial behaviors (Eisenberg et al., 2006). There is, however, a corresponding wide disagreement among researchers regarding the exact role that culture has in explaining observable phenomenological differences, and this is probably one of the reasons for which culture has played such a minimal role in the explanation of the relation between parenting and the development of prosocial behavior.

Moreover, the existing research is rather heterogeneous, both with regard to the underlying theoretical assumptions about the role of culture and with regard to the definitions and operationalizations of parenting and of the prosocial behaviors observed. Thus, whether parents differ in their behaviors and preferences for socialization strategies and whether these strategies have similar associations with children's prosocial behavior across cultures remain open questions.

In the present article, the authors use individual existing studies to create an overview of the cultural variety in parenting and prosocial behavior. Viewed in such a context, the often unrelated findings come together to suggest two general ways of cultural influence.

The authors begin with an outline of the generally accepted ideas about parenting and prosocial behaviors and then describe each of the constructs in a cultural perspective. Finally, they outline how culture, parenting, and prosocial behavior interact in concert to create diversity in forms of human cooperation and compassion.

What Is Prosocial Behavior and How Does It Develop?

Prosocial behavior is defined as 'voluntary behavior intended to benefit another' (Eisenberg et al., 2006). It is characterized by acts of kindness, compassion, and helping behaviors, which many consider to be one of the finest qualities of human nature.

Typical examples of prosocial behavior include volunteering, sharing toys, treats or food with friends, instrumental help (e.g., helping a peer with school assignments), costly help (e.g., risking own life to save others), and emotionally supporting others in distress (e.g., comforting a peer following a disappointing experience or caring for a person not feeling well). Empathy is considered as the emotion that provides both the foundation for prosocial development and the mechanism for social influence over behavior (Hastings et al., 2007).

According to both Hoffman's theory (2000) and ample empirical findings, prosocial behavior and empathy emerge early in life and develop until at least early adulthood. At its beginning, prosociality is assumed to be primarily self-oriented. It has been argued (Hoffman, 2000) that infants feel self-distress in reaction to the distress of others because they are incapable of differentiating their own experiences from those of others. Although recently evidence has accumulated showing that empathy emerges earlier than previously thought (Roth-Hanania et al., 2011), there is an overall agreement that prosocial behavior becomes increasingly other-oriented over the course of development. Gradually, self-distress is replaced by other-oriented concern, requiring some understanding of others' mental states (Hoffman, 2000). Several studies have documented the enactment of prosocial behaviors such as sharing, helping, and showing compassion as early as the second year of life and find the maximum growth in maturity and frequency of prosocial behaviors in the toddler and

preschooler period (Eisenberg et al., 2006). From childhood to adolescence, further increases are found in sharing, and less so in helping or providing emotional support. The boost in prosocial behavior with age is attributed to developmental increases in cognitive abilities associated with detecting others' needs and determining ways to help, in empathy-related responding, and in the moral understanding of the importance of helping others (Eisenberg et al., 2006).

However, because of its rather broad definition, it has been difficult to determine the exact developmental course of prosocial behavior. For example, Eisenberg and Fabes' (1998) meta-analysis found that prosocial behavior increases with age, but that the increases vary in size depending on the methodological aspects of each study. In a similar vein, investigators have not always found correlations between indices of prosociality. Prosocial behavior can include a variety of observable behaviors (e.g., helping, sharing, comforting, cooperating, and showing compassion) that may be driven by rather different motivations (e.g., the wish to benefit the other, self-interest, or practical concerns); they may be accompanied by different emotions (e.g., empathy, sympathy, or distress), and based on different cognitions (i.e., differing interpretations of situational cues). These different motivations and manifestations may reflect important distinctions for understanding prosocial behavior and its development, but relatively little socialization research has addressed this issue. There are various indications that, even within a culture, measuring prosocial behavior and development is moderated by factors such as age, sex, and the specific operationalizations involved. For example, when studying the development of children's willingness to make costly prosocial choices, it matters whether the observed child population comes from a high or a low SES background (Benenson et al., 2007). The willingness to share or to cooperate varies with the age and the sex of the person in need of it. Similarly, helping or sharing with an unknown other or with an acquaintance (Fehr et al., 2008) has neither theoretically nor practically the same meaning.

Classic operationalizations to study such voluntary prosocial acts guided by internalized values and goals rather than by the expectation of concrete or social rewards or the avoidance of punishment, include testing children's self-initiated willingness to share their resources such as food (i.e., chocolate) with an unknown stranger or to help a distressed person, who has dropped, broken, or lost something.

Such operationalizations are useful measures of spontaneous selfless acts, but admittedly they do not capture the various forms of human prosociality. Moreover, as elaborated later, neither the above-mentioned conceptualization of prosocial behavior nor the ways in which it is studied bear up in a cross-cultural comparison.

What Role Does Parenting Play in Bringing about Prosocial Behavior?

From the pioneering work of Baumrind (e.g., 1971) and Hoffman (e.g., 1970) to the present, parenting styles and techniques of discipline have been the most prominent explanatory frameworks for the development of prosocial behavior and have inspired ample research. Most of this research is based on single-time correlational studies within the well-studied postindustrialized Western information societies. Nevertheless, taken together, these studies have created a widely accepted profile of child rearing that typifies socialization of more prosocial children (see Eisenberg et al., 2006 for a review of this research).

The authors focus here on the construct of parenting styles because it represents a whole system of parent–child interaction that entails also more general aspects such as parental beliefs and more specific interaction patterns.

Research has classified the various interaction patterns according to the extent to which they reflect responsiveness and demandingness (Maccoby and Martin, 1983), or warmth and strictness (García and Garcia, 2009; Sears et al., 1957). Authoritative parents are balancing reasonable exertions of control and consistent expectations for maturity with flexibility and responsiveness to children's desires and needs. Authoritarian parents, in contrast, score higher on demandingness than on responsiveness; they "value obedience and restrict autonomy" (Baumrind, 1966: p. 890). Indulgent parents express affection to their children but show low levels of behavioral control.

In line with the idea that children will learn best socially appropriate behavior from those adults whom they have accepted as role models (Grusec and Goodnow, 1994), an authoritative parenting style has been shown to make children more receptive to efforts to foster concern for others (Hastings et al., 2000) – and identified as ultimately the best way to promote prosocial behavior. Parents of prosocial children model prosocial behavior themselves, encourage such behavior from their children and provide explanations for these expected behaviors (Hastings et al., 2007). In support of this assumption, the other parenting styles have been found to be less related to prosocial behavior and at times even as undermining the prosociality of their offspring.

The authoritarian style, for instance, has been described as believing in strict adherence to parental rules, the use of punishment (also corporal punishment) and unlikely to discuss rules with the child, behaviors that may lead children to reject instead of accept parental socialization efforts and undermine children's prosocial behavior by modeling a lack of concern for the needs of others (Hastings et al., 2006). Parental permissiveness, or indulgence, on the other hand, is viewed as leaving children without a clear sense of parental and social expectations, unsuitable to instill in children prosocial values as moral imperatives (Baumrind, 1971; Steinberg et al., 1994; Maccoby and Martin, 1983).

The notion that a democratic parenting style will be most effective in promoting prosocial behaviors is based on the idea that on the one hand too much external control will contravene internally regulated action because it impedes autonomy, and that on the other hand too little external guidance and demands will lead to undirected and aimless action. For example, self-determination theory (Deci and Ryan, 1985) has postulated that because humans share the fundamental psychological need for autonomy, children will internalize societal values and behaviors (i.e., make them their own) when parents support children's need for autonomy and foster an internalization of social rules and norms rather than

apply external pressure. Accordingly, the theory predicts less adaptive outcomes, whenever and wherever the cultural values are overly discordant with the intrinsic human nature (Grolnick et al., 1997). Indeed, the use of either physical or psychological control have been shown to have either no or negative effects on teaching prosocial behavior (Hastings et al., 2006 for a review of this research).

However, the relationship between the ways of parenting and prosocial behavior maybe culture dependent. Cross-cultural and anthropological studies have shown that cultural groups differ with regard to the emphasis they place on supporting autonomy or on fraternal submission and filial piety, which in turn will influence how much parents will focus on promotion of autonomy in their socialization practices. For example, in contrast to white middle class North Americans, who typically value assertiveness and independence in their children, parents in countries with more collectivist orientations, such as traditional China, tend to emphasize the importance of behavioral inhibition and subjugation of individual wants for the good of the family (Rothbaum et al., 2000a).

Cultures differ with regard to how they construe the self in relation to the social group, and these differing constructions create different frameworks for shaping on the one hand socialization goals and on the other hand the ideas about the ways in which these goals may be achieved (Keller et al., 2005; Keller et al., 2002; Harkness and Super, 2006) – ultimately shaping and demanding different parenting styles.

What Is Culture and How Is It Shaping Parenting?

Culture describes the 'shared symbolic system' of a community (Boesch, 1991). These systems are made up of shared language, knowledge, and networks of social relations and contain customs, laws, and beliefs. Cultural psychologists have long argued that developmental psychologists have tended to assume, if only by their restricted use of study populations, that the psychological functions they are studying have a biological basis and are therefore shared by all members of the human species (Norenzayan and Heine, 2005). This is in spite of the fact that different ecocultural environments (Berry, 1976), different socioeconomic social structures (Morelli and Tronick, 1991), or different types of community (Raval and Martini, 2009) result in different cultural models with different meaning systems that are forming the contexts for culture-specific parent–child interaction and ultimately demand different socialization styles.

In all cultures, parents interact with their children in ways that reflect their beliefs about socially appropriate behavior. Parental beliefs about child behavior and appropriate socialization goals and strategies come in part from folk knowledge about human nature and the structure of society (LeVine and White, 1987). According to Harkness and Super, parental ethnotheories are the "nexus through which elements of the larger culture are filtered" and represent central components of child development and socialization practices (Harkness et al., 2001: p. 9). A growing body of empirical studies has demonstrated that parents' beliefs about child behavior and development have important direct and indirect influences on children's cognitive, emotional, and social competence (Goodnow and Collins, 1990).

For example, the psychological assumptions about the course and pace of prosocial development and the role of democratic parenting in promoting socially adaptive development that has been reviewed above seems at least in part to be rooted in the ideas about the human nature prevailing in Western postindustrialized culture. In Western white middle class communities, prosocial socialization begins at earliest ages, is viewed as the sole responsibility of the immediate nuclear family, and as the result of a successful application of effective socialization techniques. Those beliefs and the child rearing practices that go along with them are in line with the Puritan notion of a child's nature as inherently wicked, ruthless, and selfish and the belief that only extensive socializing will "foster salvation of their souls by enforcing habits of righteousness," constituting the Protestant heritage of many Western cultures (Mosier and Rogoff, 2003).

Not all cultures believe that the child's inborn nature is selfish and that he or she has to be 'taught generosity and altruism.' The Maya in Guatemala view prosocial behavior as inherent to the social order and its development is the result of a process of gradual understanding and maturation (Mosier and Rogoff, 2003). Thus, in contrast to the notion of a need for an extensive socialization prevailing in Euro-American societies described above, children of Mayan parents do not have to be 'extensively socialized' into behaving prosocially. Similarly, in traditional Chinese families, a child's socialization is viewed as the responsibility of the community, not only of the parents, and an individual, who fails to develop adequate prosocial behaviors, is considered to be the failure of the community as a whole (Xu et al., 2007).

However, there have been relatively few studies systematically comparing parental belief systems from a cross-cultural perspective, and existing studies have focused primarily on children's cognitive development (e.g., Miller and Goodnow, 1995) rather than on social development.

The few existing studies that have examined parental beliefs about prosocial behaviors in a cross-cultural context indicate that there are significant cultural differences in the techniques used to socialize children into becoming (pro)social creatures. For example, in comparison with US mothers, Japanese mothers of young children have been found to be much less direct and forceful in their disciplinary strategies (Conroy et al., 1980; Zahn-Waxler et al., 1996). Similarly, in a cross-national comparative study of early development and socialization, Japanese mothers tended to expect obedient, self-controlled child behavior at an earlier age than US parents, whereas US parents tended to value assertive, socially skilled behavior in their young children (Hess et al., 1980).

To summarize, cultural differences with regard to customary beliefs about the human nature and its development inform culture-specific assumptions about parental strategies and mechanisms to promote children's socially adaptive development. Theorists and researchers have been arguing about the consequences of such a cultural diversity in parenting. Some researchers argue that a universal human capacity for prosocial emotions and prosocial behavior exists as part of human altruism (Hoffman, 2000), and that culture is an adaptive system of rules and practices shared by a community

(Matsumoto and Juang, 2004). Thus, culture-specific parenting styles may be just as adaptive as the authoritative style is for the well-researched White Western middle class families, as long as parenting provides the right composition of warmth and demandingness. The Nso of Cameroon, for instance, who socialize children toward obedience, respect for elders, and responsibility for others, view good parenting as the one in which parents take the lead by controlling and training the child (Yovsi et al., 2009).

Others, however, have been arguing that the idea of universality of parenting dimensions and/or of prosocial behavior is insufficient as it can neither explain the well-documented differences in prosocial behavior among cultures – which may vary both in kind and/or in amount (e.g., Knafo et al., 2009; Eisenberg et al., 2006; Whiting and Whiting, 1973) – nor can it predict individual differences in prosocial behavior within cultures (Park et al., 2012).

Does Culture Influence Prosocial Behavior?

According to Trommsdorff et al. (2007), a universal ability for altruism "cannot predict universality of prosocial behavior in different cultural contexts because (1) such behavior includes evaluations based on cultural values, self-construal, and moral beliefs; (2) cultural differences in prosocial behavior are documented (Whiting and Whiting, 1973); and (3) the concept of prosocial behavior consists of a variety of forms that makes a generalization difficult even at the individual level."

Indeed, Knafo et al. (2009) found that people from cultures high on embeddedness (e.g., Malaysia and Singapore), with a high regard for the family or extended in-group norms, were more reluctant to help strangers than people from cultures low on embeddedness (e.g., Sweden and Costa Rica) that view the autonomous individual as the key social unit. On the other hand, cultures with a high regard for the family tend to demand more and earlier of children to take responsibility for the welfare of family members and to assign chores and responsibilities in the family. The early assignment of chores and taking on responsibility for welfare of family members and the family's economic well-being appears to provide children with many more opportunities to practice and enact altruism. Several researchers have suggested that children and youth from traditional rural and semiagricultural communities and from relatively traditional subcultures are therefore more cooperative than children from urban or Westernized cultures (see Eisenberg et al., 2006 for an overview and discussion of this research). In support of this notion, Knight et al. (1982) found Mexican-American children to be more cooperative than Anglo-American children, who were found to be rather competitive. Rao and Stewart (1999) found Chinese and Indian children were more generous than middle class Western preschool-aged children. These findings appear to support the above-made postulation, but does helping a needy stranger cross the street have the same meaning as helping with the household chores or sharing food with an unknown stranger in a theoretical allocation task?

Making cross-cultural comparisons can be difficult because prosocial behavior is always measured within the context of what constitutes prosocial behavior within the context of a certain community. Using the same operationalization across cultures, such as the amount of observable helping behavior, can tell us of cross-cultural differences in the quantitative expressions of a certain type of behavior, but it might fail to capture the meaning and value the behavior has within the particular cultural system. Cultures differ considerably in their valuing of different types of prosocial action. Hindu Indians, for instance, view prosocial behavior performed because of reciprocity considerations as more moral than American adults do (Miller and Bersoff, 1994). There is reason to assume that, although sharing with an unfamiliar peer seems a good operationalization of altruistic prosocial behavior, it might not be a useful tool to study unselfish behavior in cultures in which sharing with an anonym is very unusual. Trommsdorff et al. (2007) found that children from Western cultures (i.e., Israeli and German) were significantly more willing to console a distressed adult experimenter spontaneously than were children from South Asian cultures (i.e., Indonesia and Malaysia). Such a result suggests that children from Western cultures are more prosocial than children from South Asian cultures, but it is equally possible that instead of or at least in addition to measuring spontaneous prosocial behavior, the experimental set-up also tapped cross-cultural differences in customary child–adult interactions.

In a similar vein, the prevailing theoretical view is that comforting and helping are emotion-related prosocial behaviors assumed to be strongly related with empathy. Giving and sharing, in contrast, are two qualities of prosocial behavior that are not primarily evoked by emotional reactions but are associated with a perspective of fairness and equality, which implies a more sophisticated cognitive development (Hoffman, 2000). If, however, cultures value and promote the development of different kinds of prosocial behaviors, then this conceptualization can hardly bear up in a cross-cultural comparison (Trommsdorff and Kornadt, 2003).

Studying parenting and children's behavioral outcomes in a cross-cultural context represents a key to the examination of human prosociality in its various cultural expressions.

Parenting and Prosocial Behavior in a Cross-Cultural Context: An Integration

Theorists have suggested two possible nonexclusive effects of culture on parenting and prosocial behavior.

First, the parenting styles and practices have different meaning for children's prosocial development in different cultural contexts (Kağitçibaşi, 1996). The same behavior on the part of parents conveys different meanings to children in different cultures.

Although the above description of the Western-Protestant idea about the child's inborn nature as 'selfish' and the human 'need for autonomy' is overly schematic, it is used here to exemplify how cultural ideas about the human nature are shaping theoretical as well as applied approaches to parenting and prosocial development. For example, the notion that we are born selfish has implication for when and how we will expect prosocial behaviors to develop (Hoffman, 1975, 1982) and when we will begin to teach empathy and altruism as described earlier. On the other hand, the focus on the need for

autonomy specifies that one may not enforce rules and norms if one wants to be successful in making children compassionate and kind. The implicit idea that humans are born selfish and as autonomous individuals not only implies which will be the most appropriate parenting style, but also prescribes the kind of prosocial behaviors one may observe and the motivations underlying them, and it even can serve to explain and predict the developmental course of prosocial behavior (i.e., from a self-oriented to an other-oriented prosociality) we have been observing.

Taking culture into account can help explain when Western white middle class parents, who model prosocial behavior and explain why rules are necessary rather than impose them, have children who are more prosocial than parents who use power-assertive means of socialization (e.g., Krevans and Gibbs, 1996).

In contrast to what has been found to promote and explain prosocial behavior among Western middle class offspring, research has consistently shown that Chinese parents are directive and controlling in their parenting style, rooted in the belief that rigorous and responsible teaching is reflecting high involvement with and love for their children (e.g., Chao, 1994; Wu et al., 2002). Chao (1994) has explained two culturally based concepts of parental control: 'chiao shun' and 'guanc.' 'Chiao shun' means 'training children in appropriate behaviors' (Chao, 1994). 'Guan' literally means 'to govern.' 'Guan' has a very positive connotation for the Chinese because it also can mean 'to love' or 'to care for.' Children interpret parents' firm control as an expression of their parents' care and concern. This explains why Chinese children of parents with an authoritarian parenting style may develop to share at least as willingly as American children raised with a democratic parenting style (Rao and Stewart, 1999).

Mayan parents in Mexico allow their children to decide how much to eat and sleep, whether to take medicine, and whether to go to school (Greenfield, 1999), which would be classifiable as indulgent or permissive parenting style according to Baumrind's (1971) typology, but according to Mosier and Rogoff (2003), this does not result in the above-mentioned confusion regarding societies' norms and expectations. Already by the age of 5 years, Mayan Mexican children share and care for their younger siblings, something that European-American kindergarteners are developmentally not even expected to do, and they do so in the absence of the guiding eyes of their mothers.

Thus, parental beliefs about the nature of development seem to be both the foundation and the initiator of many parent–child outcomes and they play an important role in explaining parental socialization practices and outcomes (Harkness and Super, 2006). Understanding parents' ethnotheories about their children is key to understanding the strategies parents use to help their children grow up to become successful members of their communities.

The second effect of culture on the relationship between parenting and prosocial behavior may be that cultural differences in parental socialization are the means by which cultural differences in prosocial tendencies arise (Knight et al., 1982; Whiting and Whiting, 1973). Cross-cultural perspectives on development assume that cultural emphases on particular values and socialization toward these values have an accelerating influence on the development in specific domains (Greenfield et al., 2003; Keller, 2007; Rothbaum et al., 2000b). It has been reported that in some cultures such as in West Africa, prosocial behavior is encouraged as early as infancy (e.g., infants are offered objects and then encouraged to return the gifts) to foster sharing and exchange norms believed to bind the social group together (Nsamenang, 1992).

Westerners may value prosocial acts that appear to be based on endogenous motivation more than do people from traditional cultures, whereas people from traditional cultures value prosocial actions that reflect responsiveness to others' stated needs and reciprocal obligations (Jacobsen, 1983), and this may result in different motivations and forms of prosocial behaviors.

Culture has not necessarily an influence on the existence of universal psychological and developmental phenomena but it influences their expression. Keller and Kaertner (2012) explain "Human behavior and experience are profoundly influenced by species-specific, panhuman psychological mechanisms that evolved as adaptations to solve particular challenges that our ancestors faced" (p. 66).

The profound human capacity to adapt to environmental challenges and constraints implies that development cannot be universal across different contexts. Moreover, as illustrated in the case of prosocial behavior, universal psychological processes are insufficient to explain the variety of forms in which human prosociality can be encountered. Culture is the framework that may allow us to predict the culture-specific expression of this 'panhuman' relationship.

This article is a revision of the previous edition article by A.W. Young, volume 18, pp. 12233–12236, © 2001, Elsevier Ltd.

Abstract

Prosopagnosia refers to impaired recognition of faces. The article first describes the different etiological factors and clinical phenotypes of prosopagnosia: developmental and acquired prosopagnosia for the former and apperceptive, associative, amnestic, and multimodal prosopagnosia for the latter. This includes a review of the face and function specificity of the deficit. Subsequently, the results from neuroimaging studies are discussed. The article ends with a paragraph on neurodegeneration and prosopagnosia.

Introduction

Faces are attention-getters, and this is one of the main reasons why, in social interaction and in our thinking about it, the face occupies center stage. There may also be other, quantitative, reasons why the face plays such a central role. Indeed, very few, if any, natural objects carry as much information as does the face. Whether an observer needs to know identity or gender, is wondering about age or attractiveness, is listening to speech, or is making an evaluation of trustworthiness, the gaze turns to the other's face. If only for these reasons, one understands that there is more to learn from the face than from any other source of social signals.

Two assumptions are underlying the many claims about face specificity that are at the forefront of discussions on prosopagnosia: (1) that faces trigger perceptual processes, which have category-specific markers, and (2) that faces occupy a neurofunctional niche of their own, such that neural face representation coexists with (but does not overlap with) object representation – a view that in one sense or another, it is linked to modularity or more generally to the notion of special functional units in the brain. Clinical cases constitute critical tests for theoretical models, and patients suffering from deficits in face recognition (Bodamer, 1947) have long served as an important touchstone for models of face processing.

Acquired and Developmental Prosopagnosia

Imagine that if every time you encounter the face of an acquaintance, it seemed no more familiar to you than that of a total stranger. This peculiar symptom is known as prosopagnosia – and not surprisingly, it takes a heavy toll on the social life of the patients who suffer from it. Prosopagnosics can even have difficulties recognizing people whom they are very close to, such as immediate family members, and they have to rely on other cues to identify a person – clothing, for instance, or voice. In less-radical cases, prosopagnosics are helped by the context in which they routinely encounter individuals, but they fail to recognize them when they encounter them outside the usual context – for example, when they meet a colleague in the market.

Prosopagnosia may occur after a neurological antecedent, in which case it is known as acquired prosopagnosia (AP), and is often associated with lesions in the occipito-temporal brain regions, especially in the right hemisphere (Barton et al., 2002; Damasio et al., 1982; Landis et al., 1986; Levine and Calvanio, 1989; Meadows, 1974; Sergent and Signoret, 1992; Marotta et al., 2001; Sorger et al., 2007; Steeves et al., 2006; de Gelder et al., 2003) or following a head trauma but without evident brain lesions showing up on standard imaging (Hadjikhani and de Gelder, 2003; de Gelder et al., 2003).

Prosopagnosia can also be present without any neurological history. In this case, it is known as developmental prosopagnosia (DP). However, this does not imply the absence of structural brain abnormalities. For instance, there are strong indications that congenital hypoplasia of the cerebellar vermis can be associated with face recognition difficulties (Van den Stock et al., 2012b). Patients with DP usually report lifelong problems in recognizing people by the face. DP sometimes occurs in different generations of a single family, suggesting a genetic component, more particularly an autosomal dominant mode of inheritance (Grüter et al., 2007). The term 'congenital prosopagnosia' is sometimes used to refer to prosopagnosia without any neurological antecedents. However, the congenital nature of DP is a matter of debate, and there is no conclusive evidence that all of these cases have a genetic basis. The term 'developmental prosopagnosia' has a more descriptive connotation and stresses (next to the genetic hypothesis) the possibility of a developmental disorder – for instance, in the maturation and structural connectivity of different cortical areas, such as the fusiform gyrus (Behrmann et al., 2007; Thomas et al., 2009). The pattern of deficits in AP and DP is similar as far as some basic aspects of face processing are concerned, but different in other ways (de Gelder and Rouw, 2000a).

The prosopagnosia symptom centers on recognition of personal identity but not of facial expression, and such

a dissociation has long been the cornerstone of the models of face processing in the neuropsychological literature of the last two decades, and is at the basis of the face recognition model of Bruce and Young (1986). Until recently, this dissociation was generally accepted – and as a consequence, researchers rarely investigated facial expression recognition itself, nor was much attention paid to the possibility of an interaction between the face identity and the facial expression recognition system. When problems with faces are defined as problems with identity recognition, then understanding face recognition may or may not be seen as a subspecies of object recognition. Substantial effort has gone into finding evidence for dissociations between face- and object recognition. In the 1980s and 1990s, the gold standard for supporting this kind of special or modular cognitive ability argument was to find a double dissociation. Patients with object-recognition deficits that were not prosopagnosic (as opposed to prosopagnosics without object-recognition problems) perfectly fit this bill. However such pure cases have been proved extremely rare.

Indeed, while a number of cases of prosopagnosia have been reported over the last hundred years, only very few provide evidence for pure or genuine prosopagnosia, affecting face perception in the complete absence of any other object perception deficit. Regarding the question whether prosopagnosia is exclusively a face-identity recognition deficit or whether the face recognition deficit is simply the most dominant deficit, the debate has not been concluded yet. As shown in a well-known review of the literature published at the end of the 1980s, almost all of the reported cases have associated deficits in object recognition (Farah, 1990). Lively debates will undoubtedly continue as long as new ways of testing face specificity are being developed that reflect increasingly better understanding of face recognition.

Face and Function Specificity of Prosopagnosia

Standard procedures in prosopagnosia assessment must include at least a basic screening of the visual object-recognition abilities with standard clinical test batteries such as the Birmingham Object Recognition Battery (Riddoch and Humphreys, 1993) or the Visual Object and Space Perception Battery (Warrington and James, 1991). It is not uncommon that prosopagnosics score outside of the normal range on at least one of the tests (e.g., Duchaine, 2000). Standard clinical tests for evaluating face identity matching and memory of face identity include the Benton Facial Recognition Test (Benton et al., 1983) and the Warrington Recognition Memory Test (Warrington, 1984). The scores on these tests should thus be interpreted cautiously, especially when no data are available on reaction time (as is the case for the older studies).

More modern tests and batteries are available now, targeting specific aspects of face- and object processing (de Gelder et al., 1998; de Gelder and Rouw, 2000b; Duchaine and Nakayama, 2006; de Gelder and Van den Stock, 2011; de Gelder and Bertelson, 2009). These provide a more detailed analysis of the intact and anomalous aspects of face- and object processing. The Face Emotion Action Stimulus Test (de Gelder and Van den Stock, in preparation), for example, targets a range of specific abilities including face detection, emotional face identity memory, neutral face identity memory, facial emotion matching, facial identity matching, object identity matching, facial part-to-whole matching, object part-to-whole matching, and configural face and object processing.

Since normal face processing involves multiple hierarchical and parallel processes, impairments in different processes will result in different types of behavioral and neuroanatomical correlates. In developmental disorders like DP, heterogeneity is rather the rule than the exception and this is also reflected in the behavioral findings. Extensive evaluations of single cases or small groups of prosopagnosics have found different patterns of impairment on multiple aspects of face processing, including configural processing, modulation of the N170, within-object spatial relations, recognition of emotions, gender discrimination, recognition of famous faces, holistic face processing, and facial attractiveness ratings.

There have been some attempts at making a taxonomy of the heterogeneity in clinical phenotypes associated with prosopagnosia. An older and often ignored effort at getting underneath the surface of a behavioral deficit was to understand prosopagnosia as a form of agnosia using a historical distinction between two types of agnosia, described by Lissauer (1890): (1) apperceptive agnosia reflects impairment in consciously perceiving and recognizing stimuli and (2) associative agnosia refers to a relatively preserved ability to perceive objects, but an inability to interpret what is seen or match it with its associated meaning. Apperceptive prosopagnosia therefore relates to an inability to perceive a face as an invariant face and patients suffering from this type will be mostly impaired in tasks tapping into face *detection* and face *discrimination*; whereas, associative prosopagnosia is in the first place associated with the recognition of individual faces and involves a deficit in the kind of encoding that allows telling individual exemplars apart and accessing stored representations. It is the latter type that has been mainly reported and investigated as it is assumed that prosopagnosia arises at a higher-order recognition and cognitive level. Questions about intact face detection typically are not raised in prosopagnosia and intact face detection is typically not seen as possibly a separate and earlier stage in face perception (but see de Gelder and Rouw, 2000a; de Gelder et al., 2003; Righart et al., 2010). Formal neuropsychological evaluation of associative prosopagnosia requires the use of 'semantically unique items,' i.e., stimulus exemplars that carry stimulus-specific semantic associations. In other words, the stimulus needs to have unique semantic properties that are not present in any other exemplar of the same stimulus category. Typically, famous faces figure as the preferred stimulus category for this purpose, although idiosyncratically familiar (Van den Stock et al., 2012a) or experimentally familiarized (Stollhoff et al., 2011) faces have also been used.

A less known third subtype has been proposed: amnestic prosopagnosia or prosopamnesia, which refers to the impaired ability to learn new faces. In case of acquired face recognition deficits, diagnostic criteria for a 'pure' variant would include preserved face perception, preserved memory for nonface visual material, and preserved recognition of premorbidly familiar faces (Tippett et al., 2000); whereas, for the developmental variant, the deficit would consist of abnormal processing of repeated unfamiliar faces, in combination with normal processing of familiar faces and familiar and unfamiliar nonface

visual materials (Williams et al., 2007). However, little is known about face familiarization and there is limited evidence for a clear distinction between associative and amnestic DP.

Finally, associative and apperceptive prosopagnosia are to be distinguished from impaired person recognition. There is anecdotal evidence of person recognition deficits that are not face selective and extend to voices and names (Tyrrell et al., 1990; Evans et al., 1995; Gentileschi et al., 2001; Gainotti et al., 2003). The modality specificity of the person recognition deficit would be among the main differentiating characteristics between prosopagnosia and person recognition symptoms. A multimodal person recognition deficit argues against a pure prosopagnosia. However, the majority of the studies on face recognition difficulties have only investigated the visual modality (Gainotti, 2013). In addition, cases of phonagnosia have been reported, showing impaired voice recognition, which may or may not be modality specific (Garrido et al., 2009; Hailstone et al., 2010; Van Lancker and Canter, 1982; Van Lancker et al., 1988; Van Lancker et al., 1989).

Functional Imaging Findings

The major focus of face perception research continues to be the so-called configuration-based processing or configural processing in short (Tarr, this volume). Configural processing refers to the mechanism of object perception that goes beyond the mere analysis of features or parts, but includes the analysis of spatial relations between the constituting features or parts of the object. Configural processing is most often measured by the inversion effect, which counts as the signature of intact face processing skills and it is commonly tested for in case of face recognition deficits. A few studies have reported that when a face perception disorder is present, the person or the patient does not show the normal inversion effect (de Gelder and Rouw, 2000a), but this phenomenon is also still a matter of debate (Huis in 't Veld et al., 2012). What is less clear is whether an anomaly in perceiving the face configuration and in showing the inversion effect, when confronted with neutral faces, does in fact generalize to faces where it is not the identity but the expression that matters. The available fMRI studies focusing on face perception in prosopagnosics have revealed inconsistent results (see Van den Stock et al., 2008 for an overview). In the first fMRI study with prosopagnosics, we studied activation in the occipital face area (OFA) and fusiform face area (FFA) of three prosopagnosia patients. None of them showed the normal higher activity to faces compared to objects in either region (or elsewhere). Furthermore, in two patients, there was similar activation for faces and objects in OFA and FFA (see Figure 1).

Few studies included the emotional dimension provided by a face. We investigated whether adding an emotional expression would normalize the face processing style of prosopagnosics with respect to the inversion effect. We presented neutral and emotional faces to patients with AP with lesions in

Figure 1 Activation obtained for objects (B–E) and faces (G–J) compared to control stimuli in the right hemisphere of a normal subject (B, G) and in three prosopagnosic patients (C–E, H–J). Data are represented on a flattened representation of the occipital cortex, with gyri appearing in light gray, whereas sulci are in darker gray. The dotted lines in (B) represent the major sulci (tos, transverse occipital sulcus; ips, intraparietal sulcus; its, inferior temporal sulcus; ots, occipito-temporal sulcus; los, lateral occipital sulcus; ios, inferior occipital sulcus; cs, collateral sulcus; ls, lingual sulcus). G shows the location of the different visual areas obtained by retinotopic mapping. (A) Object and (F) face show an example of the stimuli used in the experiment, and (K) is a diagram of the activation obtained for objects (in green) compared to scrambled objects and faces compared to scrambled faces (in blue and magenta) in a normal representative subject. On the upper right part of each panel, a diagram indicates the areas activated in each subject in comparison with the normal subject (K). In normal subjects, the viewing of objects compared to scrambled objects (B) elicited activation principally in the lateral occipital cortex (LO, in green in the diagram), whereas faces compared to scrambled faces activated two areas: the anterior part of the collateral sulcus and fusiform gyrus (fusiform face area (FFA), in blue) and the inferior occipital gyrus and sulcus (inferior occipital gyrus (IOG), in magenta). In patient AV, the developmental prosopagnosic, viewing both objects compared to houses (C) and faces compared to houses (H) activated the same region of the cortex, in the anterior part of the collateral sulcus and the fusiform gyrus (FFA). Objects did not produce activation in the expected LO region, and faces failed to activate the IOG area. In patient GA, injured at 18 months, faces failed to elicit any activation in the occipital cortex compared to scrambled faces (I), whereas objects compared to scrambled objects activated both the LO and the IOG area (D). Finally, patient RP, injured at 7 years, showed similar activation to both faces compared to houses (J) and objects compared to houses (E), situated in the IOG region. No activation was seen in the FFA area. None of the prosopagnosic patients showed activation in both the FFA and the IOG to face presentation. Instead they showed activation in either one or the other, or none at all.

Figure 2 Face-specific activation in the right fusiform gyrus when comparing faces (fearful/happy/neutral) with houses. Left: Areas are shown on an inflated right hemisphere. Activation maps of the control subjects are collapsed and displayed by the black contours. Activation of the individual developmental prosopagnosia subjects (DPs) is plotted in color. Right: beta values by condition, group, and DP subject. Error bars represent one standard error of the mean. Conditions represent from left to right: fearful faces, happy faces, neutral faces, fearful bodies, happy bodies, neutral bodies, and houses. White columns display the average value of the three patients. Black columns show the average value of the controls. Triangles represent the individual values of the DPs.

FFA, inferior occipital gyrus, or both. The results showed that the patients more strongly activated other face-sensitive areas like the superior temporal sulcus or amygdala when they perceive facial expressions (de Gelder et al., 2003). Furthermore, they were more accurate and faster in processing emotional faces compared to neutral faces, consistent with other studies (Duchaine et al., 2003; Jones and Tranel, 2001; Nunn et al., 2001). Since the patients in de Gelder et al. (2003) had lesions in the ventral occipito-temporal cortex, we wondered how these brain areas respond to emotional information in DP patients. Therefore, we presented a group of DPs and matched controls with fearful, happy, and neutral faces (and bodies). The results showed normal activation in FFA for emotional faces (fearful and happy), but lower activation for neutral faces, compared to controls (Van den Stock et al., 2008) (see **Figure 2**).

Prosopagnosia and Neurodegeneration

Neurodevelopmental syndromes can reveal important insights into normal cognitive functioning as selective deficits may arise in the course of neurodevelopmental syndromes, including neurodegeneration. In addition, the change in symptomatology associated with increased regional brain atrophy following progression of the neurodegenerative disease process can provide information regarding the regional involvement in cognitive functioning. While the results from studies targeting face perception in, for instance, autism spectrum disorders are heterogeneous (Barton et al., 2004), there have been recent significant advances in the characterization and categorization of dementia syndromes, for instance, concerning both language (Gorno-Tempini et al., 2011) and behavioral (Rascovsky et al., 2011) variants of frontotemporal lobar degeneration. The behavioral and neuroanatomical findings from neurodegenerative syndromes grossly mirror the apperceptive-associative-amnestic-multimodal classification of prosopagnosia. For instance, there is evidence that the neurodegenerative syndrome, known as 'posterior cortical atrophy,' is associated with apperceptive prosopagnosia and neurodegeneration of primarily occipito-temporal regions (Meek et al., 2013). There is consensus that semantic dementia, a syndrome characterized by progressive semantic deficits and anterior temporal lobe abnormalities, is associated with associative prosopagnosia (Snowden et al., 2004). A recent structural neuroimaging study in a group of neurodegenerative patients with progressive atrophy of primarily the frontal and temporal lobes provided additional evidence for the role of the anterior temporal lobes in famous face recognition: the results revealed an association between left anterior temporal lobe atrophy and famous face naming, whereas famous face recognition was related to bilateral anterior temporal lobe atrophy (Gefen et al., 2013). These results are extended by the selective progressive prosopagnosia symptomatology of an anatomical

subtype of frontotemporal neurodegeneration, characterized by predominantly right temporal lobe abnormalities as evidenced by several case reports (Evans et al., 1995; Gainotti et al., 2003; Joubert et al., 2003; Grossi et al., 2012).

However, there have been an increasing number of case reports on atypical presentations of neurodegenerative syndromes, including face perception symptomatology. For instance, we recently reported two atypical cases of Alzheimer's disease. One patient (MV) showed a mirror sign (inability to recognize one's own image in the mirror) (Van den Stock et al., 2012) and her performance on in-house custom-designed face and object processing tests was indicative of face-selective hyperfamiliarity processing with relatively intact identity recognition. The second patient (IS) displayed a particular delusion: she carried around a toy doll, of which she was convinced it was her own living grandchild (Van den Stock et al., 2013) and her neuropsychological face and object processing abilities also indicated face-selective hyperfamiliarity processing but also impaired identity recognition. These findings illustrate the heterogeneity in clinical phenotypes regarding different aspects of face and object processing.

As there is an increasing body of evidence on reports of prosopagnosia, in both scientific and nonscientific media (Della Sala and Schweinberger, 2013), the future decade holds promise regarding a better understanding of normal and abnormal face perception. But this will require putting the debate on face perception in the broader context of object recognition on the one hand, and of affect perception on the other. It is fair to conclude that for the time being, specialized studies on the localization of one, two, or more face areas in the brain have not yet moved forward our understanding of prosopagnosia.

Abstract

Prosopography, or collective biography, has developed considerably since the 1960s, expanding in the fields of modern and contemporary history, after the tool was invented and applied primarily in ancient and medieval history. The method's principle is simple: defining a population on the basis of one or several criteria and designing a relevant biographical questionnaire containing a range of variables or criteria, which serve to describe it in terms of social, private, public and/or cultural, ideological, or political dynamics. Once the documentation has been compiled, the data can be evaluated with the help of number of techniques, both quantitative and qualitative, including manual counting or computerized processing, statistical tables or factor analyses. The proliferation of studies in contemporary history and historical sociology using the prosopographic method is due to intellectual trends and techniques developed since about 1970. An overview of these is provided in this article.

Prosopography, or collective biography, has developed considerably since the 1960s, expanding in the fields of modern and contemporary history, after the tool was invented and applied primarily in ancient and medieval history. The method's principle is simple: defining a population on the basis of one or several criteria and designing a relevant biographical questionnaire containing a range of variables or criteria which serve to describe it in terms of social, private, public and/or cultural, ideological, or political dynamics. Once the documentation has been compiled, the data can be evaluated with the help of number of techniques, both quantitative and qualitative, including manual counting or computerized processing, statistical tables or factor analyses. The proliferation of studies in contemporary history and historical sociology using the prosopographic method is due to intellectual trends and techniques developed since about 1970. The concomitant decline of global statistical methods and of the intellectual impact of Marxism, and the desire, typical of societies focusing more and more on the individual, to come to grips with individual experience and the diversity of social patterns have inclined historians of recent times to emphasize social microhistory, which gives priority to prosopography or collective biography. Thanks to this technique, since the 1970s, historians have increasingly set their sights on gaining intimate knowledge of small problem-related constituencies. Some historians, such as Lawrence Stone, have criticized the method for its elitist and abstract view of society; others think that it is limited to specific privileged groups. In fact, the 1990s registered an extension to middle and lower strata of society and even a new comparative ambition, so that collective biography seems to have a fruitful prospect.

Prosopography, or collective biography, has developed considerably since the 1960s, expanding in the fields of modern and contemporary history, after the tool was invented and applied primarily in ancient and medieval history. The method's principle is simple: defining a population on the basis of one or several criteria and designing a relevant biographical questionnaire containing a range of variables or criteria, which serve to describe it in terms of social, private, public and/or cultural, ideological, or political dynamics, depending on the population under scrutiny and the questionnaire that is being used. In the words of Lawrence Stone: "Prosopography is the investigation of the common background characteristics of a group of actors in history by means of a collective study of their lives" (Stone, 1971: p. 46). Once the documentation has been compiled, which is the most time-consuming aspect of the work, the data can be evaluated with the help of a number of techniques, both quantitative and qualitative, including manual counting or computerized processing, statistical tables or factor analyses, depending on the scope and sophistication of the questionnaire and the sample.

To appreciate the success of this method and demonstrate its extension to different branches of history, several historiographic references are cited in Section Historiographic References. To gain insight into its merits and limitations, it is necessary to analyze a few examples of its application, taken primarily from recent periods see Section Merits and Limitations where other social history methods can be used, permitting us to weigh the advantages and disadvantages of both alternatives. An attempt is made to define the heretofore untapped potential of the method in the area of comparative studies in Section Toward Comparative Prosopography. This possibility has been the least explored to date.

Historiographic References

Ancient history scholars claim to be the fathers of prosopography (Chastagnol, 1970; Nicolet, 1970). The term was conspicuously used in the modern sense by T. Mommsen in the announcement of the *Prosopographia Imperii Romani*, published in 1897 (Groag and Stein, 1897; Lalouette, 1999). This serial was imitated for other periods of ancient history throughout the twentieth century, both in collective works and in individual monographs. Prime examples are *The Prosopography of the Later Roman Empire* by A.H.M. Jones and J.R. Martindale (1971–92) and *Prosopographie chrétienne du Bas-Empire*, of which two volumes have appeared, edited by André Mandouze

(1982) and Charles Pietri and Luce Pietri (1982). Countless monographs contain prosopographies of elites of antiquity. One of the earliest is Jean Kirchner's *Prosopographia attica* (1901), followed by Paul Poralla's 1913 work on the Lacedaemonians and the classics by Friedrich Münzer (1920), Ronald Syme (1939), and Claude Nicolet (1966), etc. The application of prosopography to medieval times started to develop between the world wars. Studies focus on administrative personnel and the entourage of the sovereigns of the principal Western European states. Since the 1960s, the body of literature has became quite copious, as various surveys (Bulst, 1986; Griffiths, 1986) reveal. The same goes for modern history, where the initiator was Sir Lewis Namier (1929, 1930), who studied English political elites. His works inaugurated an ongoing series of studies on the House of Commons from the Middle Ages to 1832 (Cruickshanks, 1986). French and Italian investigation has concentrated on diverse selections of officials taken from public administration and the judiciary as well as on ecclesiastical, intellectual, financial, and commercial elites (see Charle et al., 1980; Nagle, 1986).

In the area of contemporary history, work began during the second half of the 1960s. Most of it was inspired by the perspective on elites introduced by sociologists, particularly American, influenced by the theses of Pareto and Mosca beginning in the 1950s. In France, one of the issues that stimulated research of this kind was the debate on the French Revolution opened by the theses of F. Furet and D. Richet (Richet, 1969; discussed by Vovelle, 1974), proposing an alternative to the Marxist interpretation then dominant in France, founded on prosopographic study of elites before and after the upheaval. This is the background of the investigation by L. Bergeron and G. Chaussinand-Nogaret on notables of the Napoleonic Era (1979). Similar works on prominent figures of the nineteenth century and the bourgeoisie since the 1960s have relied on the prosopographic method. This approach was inspired by Ernest Labrousse (Tudesq, 1964) (for an overall survey, see Charle, 1992). French sociology of education, influenced by the works of Pierre Bourdieu (Bourdieu and Passeron, 1970; Bourdieu, 1989), has also been the source of numerous intellectual and academic prosopographies (Karady, 1972, 1973). In Britain, Germany, and the USA and more recently in Italy, Spain, and Switzerland, collective biographies of political, economic, religious, intellectual, artistic, and militant elites have proliferated. They are an outgrowth of great national historiographic debates on subjects such as the foundation of political rifts in the British parliament, the evolution and function of English nobility, the distinguishing characteristics of German, Swiss, and Italian bourgeoisies (Kocka and Frevert, 1988; Tanner, 1990; Augustine, 1994; Malatesta, 1995), the formation and reproduction of American elites (Baltzell, 1958; Jaher, 1973), and so on. In contemporary history, the method has also been applied to larger groups than elites, which are the sole focus of prosopography in the spheres of ancient, medieval, and modern history because records on other segments of the population are not available. The history of women, the middle classes, lower classes, and even marginals have also availed themselves of collective biography in recent decades thanks to abundant printed sources, oral history, and new assessments of large biographic files, which already existed (Dreyfus et al., 1996; Omnès, 1997).

Merits and Limitations

The proliferation of studies in contemporary history and historical sociology using the prosopographic method is due to intellectual trends and techniques developed since the 1970s. The concomitant decline of global statistical methods and of the intellectual impact of Marxism, which featured social classes with huge populations, and the desire, typical of societies focused more and more on the individual, to come to grips with individual experience and the diversity of social patterns have inclined historians of recent times to emphasize social microhistory, which gives priority to prosopography or collective biography. Finally, the widespread advance of computerization has facilitated complex processing of bigger and bigger databases (Stone, 1971; Millet, 1985). Whereas in former times the lack of mass documentation required patient gathering of data on the individual level before any collective generalizations could be made, in recent periods resorting to prosopography has been construed as a change of perspective from traditional social history based on serial documentation.

Thanks to this technique, since the 1970s, historians have increasingly set their sights on gaining intimate knowledge of small problem-related constituencies. Thus, S.W. Serman's study of officers of the Second Republic and the Second Empire traced the long-lasting confrontation in nineteenth-century France between the aristocratic ideal and the rising democratic tide (Serman, 1978). Investigations of elites (high-ranking personalities of the July Monarchy (Tudesq, 1964; Girard et al., 1976), the business leaders of the Second Empire (Plessis, 1985; Barjot, 1958), ruling circles of the Third Republic (Estèbe, 1982; Charle, 1987), and deputies to the national assemblies in Paris and Frankfurt in 1848–49 (Best, 1990)) were attempts to understand the evolution of models of reproduction dominant in one regime toward those prevailing in other systems, the disparity between myths justifying the social order and sociological mechanisms, the possible social impact of political revolutions, reasons for the unique French road to industrialization, the peculiar German path to an incomplete parliamentary system, and the relations between English entrepreneurs and previously dominant elites (Berghoff, 1991). In short, these collective biographies allow us to revamp our answers to some major questions as well as to conduct an in-depth reassessment of cherished tenets of social history without confining ourselves to the preconceived structure of serial and quantifiable sources. In these new approaches, groups define themselves with reference to relational characteristics or their reciprocal images or even their capacity to impose an image of themselves on others and on the majority of their members. The notion of construction of the object thus becomes decisive in this microhistory based on collective biographies.

This is precisely the point that, since 1971, has triggered premature criticism of prosopography, summed up by Lawrence Stone with reference to modern history studies inspired by Sir Lewis Namier: the biases of official sources on which the biographies rely lead to a partial view of reality, the delimitation of populations is largely arbitrary, and criteria applied for the biographies are often restrictive. All this contributes to an elitist, cynical, and conformist perspective on the spheres of leadership and their relations with society at large (Stone, 1971). These

criticisms are not valid unless the historians confuse the method with its objective and forget that they can never consider more than a fraction of reality as determined by the sources, which they select and the limitations of their biographical questionnaires. They are less likely to fall into these traps for recent periods, where the findings of collective biographies can be confronted with other sources, where partial prosopographies can be compared and merged, and where the diversity of groups readily available for investigation goes well beyond the scope of the elites to which earlier studies were confined.

The prosopographical historian navigates permanently between two reefs: the undefined biography of individuals (with the risk of losing sight of the collective dimension) and the opposite: the expansion of prolific samples to the scale of the entire society (with the risk of reducing the questionnaire to its lowest common denominator). To escape from this dilemma, collective investigation by means of large research teams, adopting common principles, has been applied with varying success in different countries. Examples include the ongoing study of the British House of Commons (Namier and Brooke, 1964), the study of mayors in France (Agulhon et al., 1986), the investigation of members of parliament of the French Third Republic (Corbin and Mayeur, 1995), the collective biographies of legislators by the Zentrum für Historische Sozialforschung in Cologne (Schröder et al., 2000; Best and Cotta, 2000). These surveys require a long-term institutional financial commitment, which has become more and more difficult to find since profitability criteria were introduced in academic research. They also assume long-term involvement of loyal research personnel, which is less and less compatible with normal levels of staff turnover. This is why the principle of coordinated monographs, being more flexible and decentralized, appears to be more realistic in the contemporary university environment. It also overcomes the need to sacrifice the originality of each individual's work in the anonymity of a hierarchic endeavor. However, to avoid the risk of dissipation or noncomparability of partial results, it posits a minimum of harmonization and entails meetings to fine-tune the common questionnaires, coding systems, and evaluations. In exploiting collective biography, one is not only forced to gauge the conditions of sample validity. One must also recognize the limits of the categories applied a priori to the data. Since the responses to the questions that are included involve social stakes, the process of interpretation of prosopographic data is characterized, more so than in other methods, by historians who consciously or unconsciously put their mark on the results at all stages of the study: sampling, data gathering, coding, and processing.

Toward Comparative Prosopography

In France and increasingly in most other developed countries, nearly all groups that lend themselves to collective biography have been adopted by a biographer: aristocracies, dignitaries, urban bourgeoisies, administrative elites, financial, commercial and entrepreneurial elites, intellectual and university elites, artists, middle-class professionals (physicians, jurists, journalists, professors), students, officeholders at all levels, labor leaders and militant feminists, even marginals, etc. Is a decline of the method of collective biography imminent? Will it be stopped in the name of the unyielding law of diminishing returns and as a result of the resurgence of historiographic topics, which are less amenable to this approach (cultural history, history of memory, history of collective sensibilities)? Three considerations allow us to reject this premature diagnosis of a decline in the advantages of a method, which has been so fruitful in the area of recent social history.

First, apart from elites, other social groups, which are beginning to revise their social history thanks to insiders' collective biographies (middle classes and, increasingly, lower classes, not only through the eyes of their militant elites, but also in the form of life stories of privileged witnesses) (Ozouf et al., 1992; Pudal, 1991; Gribaudi, 1987) are far from being thoroughly investigated. Application of the method to these new fields requires new reflection on the composition of samples (which can no longer be exhaustive) and on the relations between individual paths and morphology: the internal diversity of the configurations is directly proportional to the size of the target population. This again raises the issue of sample representativeness, which had disappeared when investigators employing prosopography of elites resorted to exhaustive polls. All these groups are transitory, while elites, by definition at the top of the heap, are target groups; hence characteristics of the individuals of which such groups are composed cannot be viewed in isolation, but must be understood as vectors of multiple strategies.

Second, European historiographers are acquainted with the adjustments required to enable them to merge complementary studies to arrive at a homogeneous scrutiny of comparable groups from different societies. Thus, the comparative research coordinated by Jürgen Kocka on European bourgeoisies has demonstrated that not all of the difficulties in analyzing this group at an international level are due to the unequal advancement of studies; above all they arise from the collateral persistence of divergent investigations – some inspired by classical methods of social history, particularly in Germanic and Anglo-Saxon countries, others, particularly in France, primarily involving research based on collective biographies, which result in different approaches to different problems, and at times to inappropriate comparisons (Kocka and Frevert, 1988; Charle, 1990).

Collective biography, therefore, still has a nearly unexploited field at its disposal: that of comparative prosopography. The principal, eternal objection to comparative historical study is the necessity, given the abundance of material, to conduct secondhand research, using monographs prepared by other scholars, with the compounded risks of hasty generalization of conclusions taken out of their unique context and of the permanent lack of correspondence in the compared data, particularly in social history, on account of the recurring coding problem. Despite these obstacles, German researchers have already forged ahead, and certain French historians and specialists in England have followed suit since the 1990s (Best, 1990; Berghoff and Möller, 1994; Charle, 1994; Siegrist, 1995; Cassis, 1997; Ruggiu, 1997). Collective biography is an extraordinarily demanding methodology in terms of research time and rigorous organization of data. Comparative prosopography multiplies the time it takes to assemble the data by at least two – for two countries – or more, if one wants to compare a greater number of cases. The problem is compounded by the

extra time needed to design the research and evaluate the data. In order to test the initial hypothesis of feasibility and fruitfulness of a comparative project, it is convenient to start in a domain where one of the two countries involved already has a critical mass of usable data allowing researchers to define an analogous scope of investigation in the other selected country, which must possess a comparable, evident interest in the chosen elite. This explains the fact that comparative prosopographies deal primarily with the best-documented and most frequently studied elites (in big business, politics, higher education, and high society), as in the cases mentioned previously. Collective biographies at a national level have permitted us to better understand the internal rifts in the various groups, which have been studied as well as their social and generational dynamics. In certain favorable cases, it has been possible to relate these rifts to political, ideological, or religious stances or apply them to better understand certain failures or successes. Comparative prosopography should allow us to go even further in this interpretive analysis by relativizing correlations, which were taken for granted in a given national or social setting. They should account for common trends that transcend borders and the peculiarities of one moment in time, of one milieu or one nation. For instance, the generally accepted notion that the expansion of higher education translates into an opening of university teaching positions to a wider segment of society is disproved if one compares the collective biographies of the professors of the University of Berlin (Arts and Sciences) with their counterparts at the Sorbonne at the turn of the nineteenth and twentieth centuries. The major divergence accounts for the misunderstandings between the two academic communities even when they attempt to cooperate, and goes a long way toward explaining their widely varying relations with other elites during political crises (Charle, 1994).

The goal of comparative prosopography, as with any kind of prosopography, is to employ collective biographies to portray the real social behavior of the institutions or the milieus in which the individual subjects of the study interact (Genet and Lottes, 1996). The main danger in applying comparative prosopography is therefore, as with many erudite ventures, that one will discover nothing but well-established or generally acknowledged truths in each country concerned. One usually arrives at this impasse or this disappointing result when one deals with samples that are too vast to lend themselves to controlled comparisons, which would allow the study to qualify any dominant feature or put it into perspective. In light of this danger it is essential to make a particularly judicious choice of variables to be compared. We face a series of common methodological issues, which transcend historical periods. Their resolution would allow us to launch a wider debate on the possible foundations of a comparative sociocultural history of European society.

Prospect Theory

Floris Heukelom, Nijmegen School of Management, Radboud University Nijmegen, Nijmegen, The Netherlands

Abstract

Daniel Kahneman and Amos Tversky's Prospect theory (1979) is to be situated in the history of probability and rational choice theory, as well as in a twentieth century American context of social engineering. As such, it is part of a vast literature encompassing psychology, economics, and mathematics, which seeks to criticize or elaborate the axiomatization of behavior as commenced by von John von Neumann and Oskar Morgenstern's *Theory of Games and Economic Behavior* and Jimmie Savage's *The Foundations of Statistics* (1954). Nevertheless, and despite an important precursor in the work of Maurice Allais (1953a,b,c, Allais and Hagen, 1979), Prospect theory was the first attempt to produce a complete descriptive theory of human decision making under uncertainty, as it deviates from the norm of expected utility theory. Since 1979, Prospect theory has seen a gradually rising recognition of theories, experiments, and discussions that further elaborate on its arguments. That being said, Prospect theory has been particularly influential in Management & Organizational Behavior and Marketing & Advertising (Note: This article draws on Heukelom (2014)).

History and Context

Two historical contexts are important for Prospect theory, that of probability theory and that of the social engineering of society. Decision theory, or the theory of risk, or rational choice theory, goes back to the second half of the seventeenth century when scholars started to investigate how to calculate mathematically the optimal decision in uncertain situations. The mathematics that came out of these and similar questions was probability theory and rational choice theory (e.g., Daston, 1988; Hacking, 1975).

A major problem confronting decision theory was what became known as the St. Petersburg Paradox, invented by Nicholas Bernoulli in 1713. Nicholas Bernoulli demonstrated that gambles could be constructed for which decision theory computed a maximum willingness to pay that was clearly at odds with intuition. The most famous solution to the St. Petersburg Paradox was offered by his cousin Daniel Bernoulli in 1738 (Bernoulli, 1954; Jorland, 1987). Daniel Bernoulli argued that individuals base their choice between two or more (uncertain) outcomes not on the monetary or objective value of the outcomes, but on their individual, subjective valuation of these outcomes. Bernoulli labeled this individual valuation 'moral value' and supposed it decreases with increasing monetary outcome, as in the curve below (**Figure 1**).

Up until the early twentieth century the literature on mathematical theories of decision making under uncertainty consisted predominantly of attempts to solve this and similar paradoxes (Edwards, 1954; Jorland, 1987).

Between the 1920s and the 1950s a number of ideas were introduced that thoroughly reshaped the way decision theorists thought about decision making under uncertainty. (This paragraph briefly indicates a few points in a large literature. Useful overviews include Eriksson and Hajek (2007), Hajek (2007), and von Plato (1994).) Authors such as Bruno de Finetti and Frank Ramsey introduced the idea that probability theory could not only be applied to objective uncertainties out there in the world, such as the probability that a coin falls heads and the probability that the sun rises tomorrow, but also to subjective probabilities, that is uncertainties inside the individual of the sort "how uncertain am I that it will rain tomorrow?" (de Finetti, 1949; Ramsey, 1931). In a related development, authors such as John Maynard Keynes and Rudolf Carnap extended the theory of logic to include uncertain propositions, that is propositions with a degree of probability that is less than 1 (Carnap, 1950; Keynes, 1921). In this logical probability approach, uncertainty stems from the subject's personal belief in the occurrence of an event. The difference between objective and subjective probability is that objective probability is a probability obtained on the basis of available information and mathematical theory, a probability that by definition is the same for all human beings. Subjective probability, on the other hand, is a number attached to the personal belief of an individual. Subjective probabilities of the same event may thus differ across individuals.

The subjectivist probability theory commenced by de Finetti and Ramsey and the logical probability approach of Keynes, Carnap, and others made statistics a part of decision theory. Decision theory was no longer only about which decision we

Figure 1 Relationship between monetary value (horizontal axis) and moral value (vertical axis; Bernoulli, D., 1954(1738). Exposition of a new theory on the measurement of risk. Econometrica 22 (1), 26; letters referred to in text Bernoulli have been removed).

as human beings should make given our preferences and the objective probability of different states of the world, it was now also about which conclusion should be inferred by statisticians from statistical data. Decision theory had incorporated statistics and was now an all-encompassing theory of human decision making under uncertainty.

However, the uncertainty employed in decision theory had always been an uncertainty external to human beings, even if individuals might assess and respond to this uncertainty in different ways. In 1944, John von Neumann and Oskar Morgenstern's *Theory of Games and Economic Behavior* added a new chapter to the history of decision theory by constructing a theory that explains human decision making in relation to the uncertainty stemming from other individuals' strategic behavior. More strongly, one could argue that von Neumann and Morgenstern started the new field of decision theory which subsequently led to the (re)discovery of a few earlier publications and developments that could be reconstructed as the field's long history.

While von Neumann was working with Morgenstern on the *Theory of Games* in Princeton in 1941, he hired a bright new research assistant from the University of Michigan, Jimmie Savage. Some 10 years later Savage published *The Foundations of Statistics* (1954) in which he tried to ground all the above developments into one overlapping theory of human decision making. Savage (1954) quickly became the central point of reference for all those working in decision theory and related areas, and for all those critical of it.

Savage's most outspoken critic during the twentieth century was Maurice Allais from the École Nationale Supérieure des Mines in Paris. Over a lunch break during the "Colloque International sur le Risque," held in Paris from 12 to 17 May 1952, Allais employed some well-chosen hypothetical choices between lotteries, which induced Savage to choose in ways that violated his own theory (Heukelom, forthcoming). The most famous pair would become the following.

Which of the following two gambles do you prefer?

1. A 100% chance at 100 million francs
2. A 89% chance at 100 million francs
   A 1% chance at nothing
   A 10% chance at 500 million francs. Savage took the exchange rate at the time to be 350 francs to the dollar, which makes the 100 million francs equal roughly 285 000 1952 dollars. Similarly, 500 million francs equals about 1 400 000 1952 dollars. Most people choose (1), which does not maximize the expected pay-off, but which may be explained as resulting from risk aversion. Now, consider the next choice.

Which of the following two gambles do you prefer?

3. A 89% chance at nothing
   A 11% chance at 100 million francs
4. A 90% chance at nothing
   A 10% chance at 500 million francs
   (Allais, 1953a: p. 527)

Here, most people choose (4), which maximizes expected pay-off and is the riskier gamble of the two. This implies that individuals maximize and nonmaximize expected monetary pay-off, and are both risk seeking and risk averse. As a result, these outcomes were considered to be a serious problem for decision theory.

Rather than admitting his theory was wrong, Savage introduced a new distinction between a normative and an empirical interpretation of the theory. Under the normative interpretation scientists and all other normal, healthy individuals determined whether these were indeed the rules to be followed, should one desire to act rationally in choice situations under uncertainty. Within the empirical domain psychologists and other empirical scientists investigated when, how, and why actual, real-world decision making behavior by individuals is in accordance with decision theory.

In turn, American psychologists who worked in a psychometric approach to psychology that was strongly influenced by nineteenth century German experimental psychology, interpreted this distinction between a normative and an empirical interpretation to be the same as their use of a normative versus a descriptive psychology. The normative and descriptive have always been closely related in psychology. In Freudian psychoanalysis as well as in military recruits' IQ testing during World War One, the object was as much to describe and classify human behavior as it was to steer it in more desirable directions. In the words of James McKeen Cattel (1860–1944), the first professor of psychology in the United States at the University of Pennsylvania, the aim of psychology was "to describe, to understand, and to control human conduct" (Cattel, 1930: p. 31).

Kahneman and Tversky

Amos Tversky received a B.A. in the human sciences from Hebrew University in Jerusalem, Israel, in 1961. His teacher Israel Gutman recommended him to mathematical psychologist Clyde Coombs, after which Tversky entered graduate school at the University of Michigan. In 1965, Tversky obtained his PhD under the supervision of Ward Edwards and Clyde Coombs, combining Coombs' mathematical psychology with Edwards' behavioral decision research. The methodological tension Tversky was struggling with in his work of the late 1960s involved the question how Savage's theory, considered to be true on the basis of introspective, or intuitive arguments, could be combined with experimental results that pointed in many directions, but only occasionally in the direction of the intuitive theory. Tversky could not proceed as an experimentalist who seeks to test whether a theory is right or wrong. As Savage's axioms were understood as introspective or intuitive truths, they could ultimately only be proven wrong on the basis of introspective or intuitive reasoning. Normative decision theory was simply not understood and employed as a theory that could be falsified experimentally. At the same time Tversky wanted to do justice to the experimental results he had obtained. Sticking to the axioms of decision theory would have implied that whenever a systematic behavioral deviation was observed in the experiments, there was something wrong with the experiment. This would mean that the majority of Tversky's experiments were invalid. Tversky was thus effectively caught between the intuitive truth of the axioms of measurement theory and decision theory, and the behavioral deviations that surfaced in his experiments.

It was Daniel Kahneman who solved Tversky's problem. Kahneman obtained a B.A. from Hebrew University in 1956 while working as a psychologist in the Israeli army. In 1958 he moved to the United States and obtained a PhD from the University of California at Berkeley in 1961 under the supervision of Susan Ervin. After completing his PhD Kahneman returned to the Psychology Department at Hebrew University where he would remain until 1978. In the meantime, however, he was among others a lecturer in the graduate program of the University of Michigan in 1968–69. While teaching at Michigan Kahneman invited his younger colleague Tversky to lecture a class on recent developments in judgment and decision making (Kahneman, 2002). In the 1960s, Kahneman's research was about semantic differentials, optometry, vision research, and related themes. Kahneman's research in this period was unrelated to mathematical psychology, unrelated to decision theory, unrelated to behavioral decision research, and despite some retrospective hints of Kahneman to the contrary, entirely unrelated to economics.

To Kahneman it was and is a given fact of life that human beings often make cognitive errors. However, science could help in two ways. First, scientists could set out what the correct way of behaving is for each situation. For a truck driver missing the traffic light, it is obvious what the correct behavior is, but for a flight instructor seeking to optimize his responses to recruits' flying performance it may not be intuitively clear what the correct way of reasoning is. Scientists can therefore help to establish the correct way of reasoning. Second, scientists, and in particular psychologists, could help by investigating when, how, and in what way human beings make cognitive errors and thus provide a basis for designing tools or education to help human beings correct these cognitive errors.

In 1969 Kahneman and Tversky started a collaboration that would result in 21 papers and 2 coedited books. They continued to cooperate on different projects until Tversky's death in 1996, but the most productive and creative period was from 1969 to 1979, including the widely cited 1974 *Science* and 1979 Prospect theory article in *Econometrica*. The cooperation was initiated by Kahneman, who was looking for new ways to experimentally test his intuition that an individual's cognitive apparatus systematically fails, and who tried to find a theory that might account for these cognitive errors. But the ensuing program stemmed as much from Tversky's growing doubts concerning Savage and Edwards' assumption that, generally speaking, individuals decide according to the normative rules of logic, Bayesian statistics, and expected utility theory (Savage, 1954; Edwards, 1954, 1961).

Prospect Theory

Kahneman and Tversky's *Prospect Theory: an Analysis of Decision under Risk* (1979) was initially entitled 'Value theory' when first submitted to *Econometrica* in 1975. Eventually, the name Prospect theory was chosen because that term did not refer to any other theory or phenomenon in economics and psychology (Kahneman, 2002). Prospect theory has often been presented as being different from Kahneman and Tversky's earlier widely cited Heuristics and Biases program (Kahneman, 2002; Tversky and Kahneman, 1974). But while it is certainly true that Prospect theory brought the different heuristics into a new overarching framework and focused on the norm of expected utility theory instead of statistics, the foundation still was the idea that human beings rely on a set of heuristics for their decision making and that the use of these heuristics sometimes leads to systematic deviations from the normatively correct decision. The 4 years between 1975 and 1979 were used to tweak a for the most part finished argument to fit an audience of not only psychologists, but also, and in particular, economists, decision theorists, mathematical psychologists, and other mathematically oriented behavioral scientists (Kahneman, 2002).

Despite an important precursor in the work of Maurice Allais (1953a,b,c; Allais and Hagen, 1979), Prospect theory was the first attempt to produce a complete descriptive theory of human decision making under uncertainty, as it deviates from the norm of expected utility theory. As in Heuristics and Biases, Kahneman and Tversky based their argument on a series of hypothetical questions they had presented to experimental subjects, in this case psychology students at Hebrew University. The problems subjects were presented with were decision problems, involving different material outcomes and different probabilities. Most of the questions were reformulations or variants of Allais' decision problems. One example of Kahneman and Tversky's use of an Allais-type approach is in the question where subjects were asked to state which of the following lottery options they preferred.

$$\text{A}: \ (4000, \ .80) \quad \text{or} \quad \text{B}: \ (3000)$$

That is, they were asked whether they preferred 4000 shekel with a probability of .8, or 3000 shekel for certain (at the time of the experiment, 4000 shekel was about one-third of the modal monthly Israeli income). Most of the subjects in this case chose B. This implied that they did not maximize the expected monetary outcome. However, opting for choice B could be explained by assuming that the decision maker was risk averse. Subsequently, subjects were asked which of the following two lottery options they preferred.

$$\text{C}: \ (4000, \ .20) \quad \text{or} \quad \text{D}: \ (3000, \ .25)$$

In this case, most of the subjects chose C and hence maximized the expected monetary outcome. This was considered problematic in combination with the first choice as it implied that subjects were sometimes risk averse, but on other occasions maximized the expected monetary outcome and hence were not risk averse. Note that the second choice is equal to the first with probabilities divided by four. With these and similar examples, Kahneman and Tversky illustrated that despite its normative status, expected utility theory as a descriptive theory was invalidated. In specific circumstances people systematically deviated from the norms of expected utility theory. A new descriptive, 'alternative account of individual decision making under risk,' was therefore required (Kahneman and Tversky, 1979: p. 274).

According to Prospect theory, a human decision maker first employs a number of heuristics to make a decision problem manageable. This process was called the editing phase. Complicated decisions are broken down into different simpler decisions, different decisions are lumped together into one big decision, a benchmark is set with which the decision is

Figure 2 A hypothetical value function. Reproduced from Kahneman, D., Tversky, A., 1979. Prospect theory: an analysis of decision under risk. Econometrica 47, 279.

Figure 3 A hypothetical weighting function. Reproduced from Kahneman, D., Tversky, A., 1979. Prospect theory: an analysis of decision under risk. Econometrica 47, 283.

compared, and so on. The purpose of this editing phase is to make the decision manageable. After this, the decision is evaluated in what was referred to as the evaluation phase. The evaluation phase has the same structure as the maximization of expected utility, but instead of the objective values of the material pay-off and probability, it uses the individual's subjective perception of the material pay-off and probability. The subjective perception of the material pay-off was referred to as value (denoted v) and the subjective perception of probability was referred to as decision weight (denoted π). In expected utility theory, a subject who is faced with a choice between outcome x that occurs with probability p and outcome y that occurs with probability q derives utility according to the following function.

$$U(x, p; y, q) = p \cdot u(x) + q \cdot u(y) \qquad [1]$$

in which utility u is a subjective valuation of the outcome according to the axioms of von Neumann and Morgenstern (1944) and Savage (1954). In other words, it defines how an individual values an outcome given its preferences if it behaves according to the normative rules of rational decision making. Furthermore, in the expected utility theory of eqn. [1] the individual perceives the probabilities of the outcomes as what they objectively are. In prospect theory, by contrast, a subject that following the editing phase faces the exact same choice values this choice according to this function.

$$V(x, p; y, q) = \pi(p)v(x) + \pi(q)v(y) \qquad [2]$$

in which v is similar to u, but based on empirical observations in experiments rather than axiomatically defined utilities; constructed with respect to an individual reference point, rather than to an objectively defined benchmark; and with a risk-seeking character in the loss domain. The experimentally derived individual perceptions of the von Neumann–Morgenstern–Savage defined utility, then, yielded the following curve (**Figure 2**).

In a similar way, and based on the same questionnaire experiments, individual's perception of the actual (i.e., objective) probabilities was inferred to be as follows (**Figure 3**).

In a clever way the opening sentences of Prospect theory alluded to frameworks of both psychologists, mathematical decision theorists, and economists.

> Expected utility theory has dominated the analysis of decision making under risk. It has been generally accepted as a normative model of rational choice, and widely applied as a descriptive model of economic behavior. Thus it is assumed that all reasonable people would wish to obey the axioms of the theory and that most people actually do, most of the time.
>
> Kahneman and Tversky, 1979: p. 263

To psychologists and decision theorists these sentences restated a well-known normative – descriptive framework that went back to Savage (1954) and Edwards (1954) in particular, and signaled a contribution to an established field of research. On the other hand, economists in the line of Friedman (1953) (in)famous positive–normative dichotomy might have raised their eyebrows at the injunction of 'normative,' but would certainly have agreed that reasonable people wish to obey the axioms of expected utility theory and that they actually do so, or at least most of the time. Note, furthermore, that Kahneman and Tversky carefully avoided the term 'rational,' and used 'reasonable' instead. Evoking the term 'rational' might have suggested that this was an article in the line of critique of economics. The use of 'rational' would certainly have induced some economists to think that these two psychologists had the same research program as Simon, who had won the Nobel memorial prize in economics the year before. From the start, prospect theory was carefully constructed so as to be able to broaden the scope to economists especially.

That said, it seems unnecessarily confusing to label the actual, descriptive valuation of the outcome of a choice by the individual 'value,' instead of utility. This was first of all part of a broader confusing use of concepts such as value and utility by psychologists and economists. At the same time, it was a clever deviation from other meanings and definitions. By making 'value' instead of 'utility' the term that referred to the

subjective attractiveness of a choice option, Kahneman and Tversky were able to design a framework that could be accepted by both psychologists and economists. To psychologists, the value framework matched the Kurt Lewinian valence framework; to economists it preserved the traditional framework of expected valuation by the individual, while at the same time allowing for the possibility that individual economic behavior deviates from the von Neumann–Morgenstern expected utility through the replacement of 'utility' with 'value.' In addition, the term 'value' was historically a central concept in economics that could be used very well to denote the pleasure an economic agent derives from choosing a specific option.

Assessment

Kahneman and Tversky's research is part of a vast literature encompassing psychology, economics, and mathematics, which seeks to criticize or elaborate the axiomatization of behavior as commenced by von Neumann and Morgenstern (2004) and Savage (1954) (Gigerenzer and Murray, 1987; Goldstein and Hogarth, 1997; Hogarth and Reder, 1987; Guala, 2005; Fishburn, 1981). Some of these contributions have been more successful than others, but arguably, few, if any, have been as successful as have been Kahneman and Tversky – as exemplified by Kahneman's 2002 Nobel memorial prize in economics and the number of times Kahneman and Tversky's work has been cited (e.g., Laibson and Zeckhauser, 1998). At the same time, Kahneman and Tversky's research has been met with substantial criticism, part of which can probably be explained by Kahneman and Tversky's success and influence itself.

The most often repeated criticism has been that Kahneman and Tversky believed people to be irrational. The argument was that if human beings can send people to the moon and return them safely, they cannot be that irrational. One of the most remarkable exponents of this view was Edwards. Edwards never elaborated upon his reservations with respect to the work of Tversky and Kahneman, perhaps from fear of losing the image of coherence of his program, yet it is no secret that he disagreed with their work (e.g., Phillips and Von Winterfeldt, 2006; Krantz – Interview, 2008; Dawes – Interview, 2008). The 1980s and 1990s gave rise to a whole surge of criticism regarding Kahneman and Tversky's approach to human decision behavior. The most prominent philosophical critique was provided by Cohen (1981). The most extensive criticisms from within experimental psychology came from Gerd Gigerenzer who questioned the set-up and interpretation of Kahneman and Tversky's experiments, and who wondered how people manage to travel to the moon if they are so bad at assessing uncertainties (e.g., Gigerenzer, 1991, 1993, 1996; Gigerenzer and Murray, 1987; Sedlmeier and Gigerenzer, 1997, 2000; Hertwig and Gigerenzer, 1999). Gigerenzer has been the only critic to whom Kahneman and Tversky have explicitly responded (Kahneman and Tversky, 1996). Other critics include Lopes (1991) and Cosmides and Tooby (1996). The most salient question pertaining to the work of the two psychologists is therefore why they were successful where others were less successful, despite the broad range of critique they received. In my opinion, three aspects stand out in particular. (See Hands, 2011 for further explanations.)

Friendly Criticism and the Normative–Descriptive Shuffle

In prospect theory Kahneman and Tversky employed the standard normative – descriptive distinction of experimental psychology, behavioral decision research, and mathematical psychology, and assumed that economists would employ the very same distinction. This partly reflected a standard understanding of economics in behavioral decision research and psychology. One possible conclusion therefore is that Kahneman and Tversky were not familiar with economists' use of positive and normative, and understood these terms to mean the same thing as the descriptive and normative of behavioral decision research. But Kahneman and Tversky's use of normative and descriptive can also be seen as a very clever way of trying to convince economists of the relevance of Prospect theory for economics. In Prospect theory, Kahneman and Tversky did not tell the economists that their theory was complete nonsense or useless. Instead, they claimed to understand economics as using one theory to cover both the normative and the descriptive realm. For the normative part they fully agreed with economists, which fitted in neatly with practice in behavioral decision research. But, Kahneman and Tversky argued, economists had been mistaken in using that same theory in the descriptive domain.

Put differently, according to Kahneman and Tversky there was nothing wrong with economists' theory of expected utility maximization. It was only that this was the normative theory, and not an accurate description of actually observed human behavior. Economists did not need to abandon the theory of expected utility maximization, but instead they should seek a proper descriptive counterpart to this normative theory. A first explanation for Kahneman and Tversky's success among economists is that they provided a relatively friendly criticism which allowed expected utility theory a life under the rubric of the normative theory. Moreover, they offered an alternative for the descriptive realm in the form of prospect theory that closely resembled expected utility theory.

The Role of the New Type of Experiments

A second reason for the success of Prospect theory's perspective of human decision making were the type of experiments employed. In their collaborative research during the 1970s, Kahneman and Tversky conducted different kinds of experiments than the two had done individually in the 1960s. From the early 1970s onward, the experiments consisted of questionnaires with hypothetical questions which mainly students were asked to fill out. These questionnaires could be distributed anywhere, to participants at conferences, to students during a course at the university, and in a shopping mall on a Saturday afternoon. These questionnaire experiments provided only copies of the questionnaires and pens to fill them out. No separate laboratory space was needed and no payment of the experimental subjects was required, filling out the questionnaires took a few minutes at the most. In the 1979 Prospect theory article, Kahneman and Tversky defended their new method of experimentation and contrasted it with two other

methods of investigation. First they distinguished the possibility of 'field studies,' which used 'naturalistic or statistical observation' that could yield important insights when a new area of research was opened, but in the end could only provide "crude tests of qualitative predictions, because probabilities and utilities cannot be adequately measured" (Kahneman and Tversky, 1979: p. 265). Second, they recognized the method of laboratory experiments, which had the disadvantages that stakes could only be relatively small and that for financial reasons it was difficult to conduct an experiment in which the subjects were asked to choose between, say, $300 for certain or a .8 chance at obtaining $400. The third method, which they argued proved to be the best for solving the problem they were investigating, was 'the method of hypothetical choices.' It solved the problem of the absence of control of field studies, while at the same time solving the external validity problem of laboratory experiments. It did however rely on the assumption that people "know how they would behave in actual situations of choice" and that they "have no special reason to disguise their true preferences" (Kahneman and Tversky, 1979: p. 265).

There is not a direct link between Prospect theory, and the new, more relaxed standards of the experimental method. That is to say, Prospect theory could, in theory, have been developed without the new means of conducting experiments. But the new standards of experimental control facilitated Kahneman and Tversky's research in fundamental ways. It is safe to say that, without the method of hypothetical questions they could not have developed heuristics and biases and prospect theory. Thus, although there is not a direct link between Kahneman and Tversky's Prospect theory and their experimental method, it is difficult to see how they could have been tested and developed without this new method. The success of Kahneman and Tversky's new program is hence in part explained by the new experimental methodology they employed.

Intuitively Appealing Examples

A third reason for Kahneman and Tversky's success is their effective use of intuitively appealing examples. Typically, the argument in Kahneman and Tversky's research was made not so much by giving theoretical explanations for why such and such was a good theory or account of observed behavior, but by supplying examples of the experimental questions subjects had been asked which were meant to give the reader an intuitive understanding of the point they were trying to make. The appeal of the examples employed gradually developed over time. The best known query among the many experimental questions of Kahneman and Tversky became the so-called 'Linda problem,' no less because it was often used by Kahneman and Tversky's adversaries. The Linda problem runs as follows:

Linda is 31 years old, single, outspoken and very bright. She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations.

Which of the following two alternatives is more probable:

1. Linda is a bank teller.
2. Linda is a bank teller and active in the feminist movement (Tversky and Kahneman, 1983: pp. 297, 299).

On average, there was a strong bias toward judging (2) to be more probable than (1), this despite the fact that (2) is logically contained in (1). Because this bias is an illustration of the failure to see that the probability of the conjunction of two or more events can never exceed the probability of one of the events, this bias was labeled the conjunction fallacy.

The appeal and intuition of these examples provide a third explanation for Kahneman and Tversky's success, because the readers of their articles could relate the examples to their own everyday decision making. It was also via these intuitive examples that Kahneman and Tversky received some strong opposition in the 1980s and 1990s. Kahneman and Tversky's adversaries typically proceeded by deconstructing their examples and illustrations, or by giving counterexamples. It was for instance shown that a different conclusion could be inferred from the observed behavior, or that responses to another set of hypothetical questions falsified Kahneman and Tversky's conclusions (e.g., Gigerenzer, 1991, 1993, 1996; Hertwig and Gigerenzer, 1999; Lopes, 1991).

Influence in Behavioral and Social Sciences

The term 'Prospect theory' is only associated with the theory by Kahneman and Tversky. As a result, a first, rough indication of its rise and spreading after its introduction in 1979 is a standard Google ngram search. Figure 4 presents the

Figure 4 Google ngram moving average of 2 years.

Figure 5 Total citations 'prospect theory' full text.

results for the combined appearance in the Google Books project of either prospect theory, Prospect theory, or Prospect Theory (ngram is case sensitive), with a moving average of 2 years.

Because Google ngram reports appearance of terms as a percentage of total available Google books, the outcome is not sensitive to a general rise in the number of books over the years. The results indicate a gradually rising recognition of prospect theory and of theories, experiments, and discussions that further elaborate on its arguments.

An alternative quantitative suggestion at the rise and spreading of prospect theory may be obtained through Jstor – which includes the vast majority of scientific articles, books, pamphlets, reviews, and other science-related publications. A minor drawback is that while Jstor offers the contents of some journal until early 2013 (at the time of writing), most are only available through 2010, while a substantial number does not run further than 2009 or 2008. To be on the safe side regarding the general trend, it seems better not to look beyond 2007. A full-text search of all published material available in Jstor up to 2007, then, yields the following result (Figure 5).

Unlike Google ngram, a Jstor search does not discount for a general rise in published and/or available sources over the period investigated. Nevertheless, it seems safe to conclude the results indicate a trend similar to that of Figure 4.

Table 1 Citations 'prospect theory' Jstor, full text, 1979–2007. Due to overlap, the sum of the subcategories listed is larger than the total number of citations

Category	*Number titles*	*Number citations*	*Citations/ titles*
Marketing and advertising	14	199	14.2
Management and organizational behavior	31	418	13.5
Business	235	1346	5.7
Psychology	18	95	5.3
Finance	31	100	3.2
Economics	173	543	3.1
Political science	152	406	2.7
Law	97	202	2.1
Sociology	128	233	1.8
Public policy and administration	38	53	1.4
Philosophy	99	56	0.6
Sum Subcategories	1016	3651	3.6
Total	1695	2128	1.3

In addition, Jstor permits us to derive some indication of the relative impact of Prospect theory in various scientific fields. A difficulty here is that the categories defined by Jstor include some overlap. The journal *Econometrica*, for instance, is both listed in the category of Economics and in the category of Mathematics. As a result, while the total references to Prospect theory in Jstor from 1979 to 2007 is 2128, the sum of the citations in the Jstor-subcategories with the most references to Prospect theory equals 3651 – as reported in the bottom two rows of Table 1 below. A second nuance is that the number of titles included in each category varies widely, from 235 in Business to 14 in Marketing and Advertising. This may be solved by calculating the citations per journal in each category. However, the number of issues a journal publishes per year, the number of articles per journal, and the number of citations per article may differ between categories. These variations cannot be controlled for. Finally, Jstor does not indicate how well it represents each discipline.

Figure 6 Citations/title per Jstor category, 1979–2007, moving average 3 years, except 1980 (2 years) and 1979 (1 year).

That being said, a subdivision of Jstor Prospect theory full-text appearances offers some hints as to the general pattern. First of all, Figure 3 shows Prospect theory has had a wide impact in the social sciences and related fields. Even relatively remote fields such as Philosophy and Sociology have produced substantial numbers of references to Prospect theory. But, secondly, the table also indicates the impact of Prospect theory to vary widely between fields. Judged by citations per title, a field such as Philosophy has produced the occasional discussion of and reference to Prospect theory, while Prospect theory has become part of the standard vocabulary in Management and Organizational Behavior and Marketing and Advertising. The contrast with Psychology and Economics is striking. Kahneman and Tversky were psychologists, who published in psychological and economic journals. Moreover, in 2002 Kahneman received the Nobel prize for Economics. Yet, while both Psychology and Economics produce substantial numbers of citations of Prospect theory, it had its largest impact outside of those two fields. The case apart of Business confirms these signals. The number of citations in Business is the largest by far, but is the product of 235 titles. As a result, it seems not unlikely that reasonable subcategories of Business could be defined with varying levels of Prospect theory citations. Given that parts of Business are closely related to Management and Organizational Behavior and Marketing and Advertising, the numbers for Business to further emphasize the relative impact of Prospect theory in these fields (Figure 6).

Finally, tracing the citations per title over time, as in Table 1, does not yield unambiguous results. The graphs seem to suggest that the popularity of Prospect theory in psychology is past its peak, while its popularity in other fields continues to rise. A final assessment, however, will have to await the third edition of this encyclopedia.

Abstract

Prospective memory refers to the ability to remember to perform delayed intentions such as remembering to take medication. Prospective memory is dissociable from other forms of memory by its future focus, the need for planning, and a reliance on self-initiated retrieval. Current theoretical approaches examine whether prospective memory is supported by effortful monitoring (anterior prefrontal cortex), relatively automatic spontaneous retrieval (hippocampus), or both. Conditions that have an impact on these processes (and supporting neural structures), such as substance abuse, neurodegenerative diseases, and aging, are associated with prospective memory impairments. Forming specific plans, avoiding interruptions, and relying on salient external cues can improve prospective remembering.

The ability to remember is one of the brain's most important functions, and thus memory research has been at the forefront of psychological science for over 125 years. Historically, most memory research has focused on retrospective memory, or memory for past events, such as remembering a baseball game you went to with your father as a child. Whereas retrospective memory captures our ability to recollect what has occurred in the past, researchers have begun to recognize the many other adaptive uses to which memory is put, such as enabling individuals to recall at the correct moment an intention that they need to perform (e.g., silencing a cell phone when entering a classroom). The ability to remember to perform delayed intentions is referred to as prospective memory.

Prospective memory is ubiquitous in our daily lives. We rely on prospective memory to meet social needs such as remembering to wish a friend a happy birthday; to perform daily chores such as remembering to start the dishwasher before going to bed; to excel in the workplace by remembering to follow through on assigned tasks that cannot immediately be performed; and to maintain health by remembering to take medications with dinner. Because a great deal of each day is spent forming intentions and acting on those intentions, it is no surprise that failures in prospective memory constitute at least half of everyday forgetting (Crovitz and Daniel, 1984).

Failures in prospective memory can have critical, even life-threatening consequences. One epidemiological study found that forgetting to take one's blood pressure medication at least one time significantly increased the risk of heart attack and death (Nelson et al., 2006). Prospective memory is also important in the workplace. For example, in the intensive care unit, nurses have many health-relevant prospective memory demands. Failing to remember to deliver medications, to redress wounds, or to properly chart changes in vital signs can result in poor health outcomes for the patient. Moreover, in aviation, aircraft pilots must remember to perform several actions sequentially prior to take-off and landing and failure to remember to perform any of these actions may result in injury or death. Although airline accidents are rare, Dismukes (2006) observed that almost one-fifth of major airline accidents can be attributed to prospective memory failures. Thus, prospective memory is not only ubiquitous in our lives, but it is also important to maintaining health and safety (Dismukes, 2012).

The Empirical Study of Prospective Memory

Early prospective memory research assessed the frequency of failures in prospective memory relative to other kinds of memory. These were typically diary studies in which participants recorded all of their memory failures during a set period of time. In one diary study, Terry (1988) observed that 70% of daily forgetting errors were related to prospective memory, indicating that prospective memory has been underrepresented in memory research.

The identification of prospective memory as an under-recognized topic helped to spark several objective research studies. The first objective studies of prospective memory took a seminaturalistic approach, asking participants to mail postcards (Meacham and Singer, 1977) or to call the laboratory (Moscovitch, 1982) at predetermined times. These studies effectively captured some of the naturalistic components of prospective memory tasks and stimulated interest in factors thought to influence prospective remembering (e.g., the age of the participants), but they were limited by a lack of experimenter control over the use of external aids such as calendars.

Laboratory Approaches

The introduction of laboratory paradigms (Einstein and McDaniel, 1990; Kvavilashvili, 1987) for studying prospective memory greatly promoted research by allowing experimenters the ability to control and manipulate variables hypothesized to have influence on prospective remembering. In the typical laboratory paradigm, participants are first busily engaged in an ongoing decision-making task such as rating the pleasantness of words. After receiving ongoing task instructions, participants receive instructions to perform an unrelated task at some predetermined point in the future – for

 http://dx.doi.org/10.1016/B978-0-08-097086-8.51055-1

example, to press the *Q* key when the word *coffee* appears during the pleasantness-rating trials. The prospective memory action (e.g., press the *Q* key) is usually designed to be simple and easy to remember. By keeping the contents of the intention simple (i.e., the retrospective component of the prospective memory task), researchers are better able to isolate the components that are unique to prospective memory.

Distinguishing Characteristics of Prospective Memory

There are three primary distinguishing features of a prospective memory task. First, whereas retrospective memory tasks are past-focused, prospective memory tasks are future-focused. Second, prospective memory tasks (e.g., press *Q* for *coffee*) are always embedded within an ongoing activity (e.g., pleasantness rating), and they require the interruption of that ongoing activity. The purpose here is to simulate real-life prospective memory situations in which people are actively engaged in an ongoing activity (e.g., driving home), but must suspend that activity in order to perform a prospective memory intention (e.g., stopping at the post office). The third, and perhaps most important, distinguishing feature of prospective memory tasks is that retrieval of the prospective memory intention is self-initiated. When the appropriate cue to perform the intended action occurs (e.g., the word *coffee*), there is no explicit prompt to perform the prospective memory task. Unlike in cued recall (retrospective memory), where the experimenter gives participants a cue word and specifically asks the participant to retrieve the associated word, in a prospective memory task, participants must switch (without external prompting) from seeing the prospective memory cue as another ongoing task stimulus to a cue to initiate the intended action. Therefore, prospective memory is often referred to as the ability to 'remember to remember.'

Categories of Prospective Memory Tasks

Although all prospective memory tasks are future-focused, embedded within an ongoing activity, and require self-initiated retrieval, subcategories of prospective memory tasks have emerged. In 'event-based' tasks, an environmental cue indicates that the prospective memory action should be performed (in the above example, the word *coffee* is an event-based cue). Real-world event-based prospective memory tasks include remembering to deliver a message (intention) when you see your friend (cue) and remembering to turn off to go to the grocery store (intention) when driving by a particular intersection (cue). Prospective memory tasks may also be 'time-based.' In time-based prospective memory tasks, one must remember to perform the prospective memory response after a certain length of time has elapsed. For example, to chill a can of soda, one might place it in the freezer with the intention of removing it in approximately 20 min (failing to remember would result in a sticky mess to clean up).

The Stages of Prospective Memory

Like retrospective memory, prospective memory also can be described in terms of three stages: encoding, storage, and retrieval. Research has focused on understanding the differences between retrospective memory and prospective memory at each of these stages. These differences are illustrated in Figure 1.

Encoding

One of the key functions of episodic memory is planning for future events (Klein et al., 2010). Yet, planning is rarely incorporated into traditional retrospective memory tests. By contrast, encoding a prospective memory intention may involve a high degree of planning (Figure 1). For example, one must plan how and when to accomplish the intention – such information is typically not necessary to consider when encoding information in retrospective memory. The precise amount of planning involved, however, varies greatly across prospective memory tasks. For example, remembering to remove pasta from the cooktop after 10 min may require little planning when that is the only item that you are preparing for dinner, but fulfilling the same intention may require more planning when you are also busily preparing vegetables, fish, and dessert.

Research on the planning phase of prospective memory has yielded two general conclusions. First, there are clear individual differences in the quality and complexity of the plans forged to complete intentions (Kliegel et al., 2000). Second, though individuals commonly form general prospective memory intentions, such as "I want to exercise more," these general intentions are often never initiated. A far more effective prospective memory encoding strategy, which is referred to as implementation intention encoding, is to form a very specific plan (e.g., "I will go to the gym to use the treadmill at 2 p.m. after my Chemistry class"; Gollwitzer, 1999). Implementation intention research is described more fully in the Improving Prospective Memory section.

Storage

The storage of prospective memories is in some ways similar to the storage of retrospective memories (Figure 1). For example, nocturnal sleep benefits the consolidation, or the long-term storage, of both prospective and retrospective memories (Scullin and McDaniel, 2010). Slow-wave sleep may be particularly important for consolidation of both retrospective and prospective memories (Diekelmann et al., 2013). Despite this similarity, research on the shorter-term storage of memories suggests that prospective memory storage has at least two characteristics that distinguish it from retrospective memory storage. Whereas retrospective memory has long been known to decline across increasing retention intervals (Ebbinghaus, 1885/1964), prospective memory may decline, remain stable, or even increase with longer retention intervals (Hicks et al., 2000; Martin et al., 2011). In addition, studies of levels of memory activation suggest that prospective memory intentions are stored at a higher state of activation than other memory contents. Research shows that, following encoding of a prospective memory intention, participants are faster to respond to words that are associated with their intention during recognition tasks (Goschke and Kuhl, 1993) and lexical decision tasks (Marsh et al., 1998). These 'intention superiority' effects are only observed when the individual will personally perform the intention, and not when the individual is expecting to watch someone else perform the intention, or when the

Figure 1 The stages of prospective memories and retrospective memories. Many factors distinguish the encoding, storage, and retrieval stages of prospective memories from retrospective memories.

intention has already been completed (Scullin et al., 2009). Thus, to-be-performed prospective memory intentions exist at a heightened level of activation, and this intention superiority allows intentions to come to mind quickly in response to relevant environmental cues (Goschke and Kuhl, 1993).

Retrieval

The most critical distinguishing feature of prospective memory tasks is that retrieval is self-initiated (Figure 1). Accordingly, much research has focused on understanding the processes operating at prospective memory retrieval. One possibility is that, after forming a prospective memory intention, people begin to engage attentional resources to monitor the environment for the appropriate time/cue to carry out the action. The Test-Wait-Test-Exit model (Harris, 1984; Harris and Wilkins, 1982) contends that people periodically 'test' whether it is the appropriate time to carry out their intention. In this scenario, an individual self-initiates prospective memory retrieval and determines ('tests') whether it is time to perform the intended action. If a 'test' reveals that it is too early to perform the intended action, then normal activities are resumed until another 'test' is initiated. If the 'test' reveals that it is time to perform the intended action, then the action is performed and the intention is disengaged ('exited'). In time-based prospective memory tasks, participants may engage in periodic clock-checking behavior to determine whether it is the appropriate time to perform the action (e.g., "Is it time to remove the soda from the freezer?"). People typically engage in more frequent clock-checking behavior as the time to perform the intention approaches, and this strategic increase in clock checking is associated with better prospective memory performance (Harris and Wilkins, 1982). The Test-Wait-Test-Exit model has received empirical support for time-based prospective memories. The primary limitation of the Test-Wait-Test-Exit model is that it does not specify a mechanism for how people self-initiate the 'test.'

Preparatory Attentional and Memory Processes Theory

One possibility is that the cognitive system actively searches for cues that signal that the prospective memory intention should be performed. For example, the preparatory attentional and memory processes (PAM) theory (Smith, 2003), which may be conceptualized as an extrapolation of the Test-Wait-Test-Exit model (Harris and Wilkins, 1982) to event-based prospective memory, contends that people will periodically recollect their plans (cf 'test'), which can subsequently lead the individual to monitor their environment for cues that signal that the prospective memory intention should be performed. Consider the concrete example of remembering to buy a loaf of bread on the way home. The PAM theory assumes that we periodically self-initiate retrieval of this plan

throughout the day (e.g., during breaks when we consider "what we later have to do"), and if we later self-initiate retrieval of the plan when we are driving home then we will begin to monitor the environment for signs of the grocery store. An important component of the PAM theory is that prospective memory retrieval cannot occur in the absence of monitoring and that failures in prospective memory are due either to lapses in devoting attentional resources to monitoring or to a retrospective memory loss of the contents of the intention (e.g., forgetting that it is bread that needs to be purchased from the grocery store).

Support for the PAM theory of prospective memory monitoring comes from studies showing that trying to remember to perform a prospective memory intention can detract attention from other ongoing activities. The argument is that monitoring is effortful and requires attentional resources that could otherwise be devoted toward efficiently making ongoing task decisions. Therefore, if one is monitoring for the grocery store on the way home, then one's driving performance might be impaired. Consistent with this argument, participants who have a prospective memory demand often perform an ongoing task more slowly or less accurately than participants who perform the same ongoing task alone (e.g., Marsh et al., 2003; Park et al., 1997; Smith, 2003).

Multiprocess Theory

Like the PAM theory, the multiprocess theory (McDaniel and Einstein, 2000) assumes that prospective memory retrieval is sometimes accomplished via attentionally demanding monitoring processes. An important difference between these theories, however, is that the multiprocess theory also assumes that relatively automatic, 'spontaneous retrieval' processes can support many instances of prospective remembering. This view arises from the observation that people often have multiple prospective memory demands, many of which may not be executed for hours or days (e.g., remembering to call your grandmother on her birthday), and it is often difficult to precisely anticipate when a prospective memory action can be completed (e.g., delivering a message to a colleague at some point while at work). For these reasons, it seems unlikely that people would (or could) engage in attentionally demanding monitoring processes to remember all of their prospective memory intentions all of the time. But, if people can still remember to perform prospective memory intentions even if they do not constantly monitor, then there must also exist a less-effortful retrieval mechanism. The multiprocess theory contends that in the absence of monitoring, environmental cues that are strongly associated with a prospective memory intention can stimulate the retrieval of the associated intention (spontaneous retrieval). For example, after forming the intention to invite a friend to an upcoming party, passing by that friend in the hallway may cause the associated intention to spontaneously 'pop' into conscious awareness (for an analog in the autobiographical memory literature, see Berntsen, 2009).

The question of whether the occurrence of a target event (e.g., the grocery store) that has been associated with an intention can spontaneously trigger retrieval of an episodic memory (e.g., the intention to stop at the store and buy bread) is theoretically interesting. On the one hand, stimuli in our environment rarely distract us from the task at hand: When enjoying a conversation with a friend in a restaurant, the objects and events in our surroundings usually do not elicit extraneous episodic memories (except for individuals with posttraumatic stress disorder; Berntsen, 2010). Based partially on this observation, Tulving (1983) proposed the interesting idea that retrieval does not occur unless we are in a 'retrieval mode.' From this retrieval-mode perspective, you have to be trying to remember (e.g., engaging preparatory attentional processes) in order to retrieve an intention in response to processing a target event. By contrast, the multiprocess theory proposes that being in a retrieval mode is not a condition for episodic memory retrieval and that cues associated with intentions can spontaneously trigger retrieval of those intentions.

Recent research has provided strong evidence that spontaneous retrieval processes support many instances of prospective remembering. The overall approach in these studies is to create conditions of no monitoring and to examine whether successful prospective remembering occurs in the absence of monitoring. In a series of experiments that are illustrated in Figure 2, Scullin et al. (2010) eliminated monitoring by requiring participants to perform a block of over 500 ongoing task trials. Because monitoring is effortful, people are typically unable to sustain monitoring over long blocks of trials, especially when monitoring is unreinforced (i.e., when there are no opportunities to perform the prospective memory task). By the end of the block monitoring had dissipated completely, yet when a strong ('focal') prospective memory cue was presented on Trial 501, 73% of participants still remembered to perform the prospective memory action. The participants who successfully remembered to perform the prospective memory action showed no evidence for monitoring proximal to Trial 501. Therefore, monitoring is not always required for successful prospective remembering; in the absence of monitoring, seeing the sign for the grocery store can spontaneously trigger retrieval of the associated intention to pick up bread.

Given the findings that prospective memory is sometimes supported by monitoring and other times supported by spontaneous retrieval, much research has been devoted to identifying and examining factors that determine reliance on these retrieval processes (e.g., Einstein et al., 2005). For example, people are more likely to monitor when the importance of the prospective memory task is emphasized and when the prospective memory task must be performed often. Conversely, reliance on spontaneous retrieval is greater when there is a long delay between the formation of the intention and the opportunity to complete that action, and also when the ongoing task encourages focal processing of the prospective memory cues (i.e., processing of the relevant features of the cues that were also processed at encoding), which is demonstrated in Figure 2. The most recent development of the multiprocess theory contends that monitoring and spontaneous retrieval processes interact dynamically to support prospective memory in naturalistic settings (Scullin et al., 2013).

Neural Correlates of Prospective Memory

Much of the existing research on prospective memory has been behavioral, but there is now growing interest in understanding the neural underpinnings of prospective memory. Such

Figure 2 (a) Participants encoded either a focal or a nonfocal prospective memory task (or no prospective memory task, as in the control condition) and then (b) were tested following a short or long retention interval. (c) The results showed that because monitoring is resource-consuming it wanes over time when the prospective memory intention is not actively being performed (zero cost indicates no monitoring). (d) When monitoring is absent (focal condition, Trial 501), spontaneous retrieval processes can still support prospective memory retrieval in response to good retrieval cues (focal cues). However, prospective memory performance in response to poor retrieval cues (nonfocal cues) drops dramatically when monitoring is reduced. Adapted from Scullin, M.K., McDaniel, M.A., Shelton, J.T., Lee, J.H., 2010. Focal/nonfocal cue effects in prospective memory: monitoring difficulty or different retrieval processes? Journal of Experimental Psychology: Learning, Memory, and Cognition 36, 736–749, (Experiments 3 and 4).

research has primarily focused on the retrieval phase of prospective memory rather than on encoding or storage stages. The literature suggests that two structures, the anterior prefrontal cortex and the medial temporal lobe, may be critical for monitoring and spontaneous retrieval, respectively.

Anterior Prefrontal Cortex

The anterior prefrontal cortex has been implicated in executive control functions, which thereby makes it a candidate for supporting effortful prospective memory monitoring processes. Case studies of prospective memory have supported this idea. For example, Burgess et al. (2000) found that patients with lesions in areas including the anterior prefrontal cortex demonstrated more prospective memory impairments in a task that required effortful monitoring than age- and intelligence-matched controls.

Human neuroimaging studies have further supported a role for the anterior prefrontal cortex in prospective memory. Using positron emission tomography (PET), Burgess et al. (2001) found that the anterior prefrontal cortex demonstrated greater activation during intervals in which an individual was monitoring for a prospective memory intention than during a baseline interval in which there was no prospective memory intention. In addition, using functional magnetic resonance imaging, Reynolds et al. (2009) also demonstrated that the anterior prefrontal cortex is engaged to support prospective memory monitoring, and that the neural signature of prospective memory monitoring is distinct from other cognitive constructs such as vigilance and working memory. All existing functional neuroimaging prospective memory studies have been conducted on event-based prospective memory. Whether time-based prospective memories are supported by the same anterior prefrontal cortex system is an open question.

Medial Temporal Lobe

Neuropsychological studies of prospective memory have also investigated the role of the medial temporal lobe in supporting spontaneous retrieval of intentions. The medial temporal lobe, which includes the hippocampus, has previously been implicated as a structure that supports reflexive-associative retrieval (Moscovitch, 1994). Evidence for a role of the medial temporal lobe in spontaneous retrieval of prospective memories arises from studies of clinical populations. Individuals who show a very early stage of dementia of the Alzheimer's type are also highly likely to show medial temporal lobe declines, but perhaps not prefrontal cortex declines, relative to age-matched controls (Buckner, 2004). Therefore, such patients provide a useful model for testing the role of the medial temporal lobe in prospective memory. As illustrated in

Figure 3 Very mild dementia of the Alzheimer's type is associated with declines in focal prospective memory (spontaneous retrieval) but not nonfocal prospective memory (monitoring). This figure was modified from McDaniel, M.A., Shelton, J.T., Breneiser, J.E., Moynan, S., Balota, D.A., 2011. Focal and nonfocal prospective memory performance in very mild dementia: a signature decline. Neuropsychology 25, 387–396.

Figure 3, McDaniel et al. (2011) found that patients with very mild Alzheimer's disease performed worse than healthy control participants on a prospective memory test that relied on spontaneous retrieval (focal prospective memory), but not on a test that relied on monitoring (nonfocal prospective memory). These results were consistent with the idea that the medial temporal lobe is a critical structure for supporting spontaneous retrieval of prospective memories.

Gordon et al. (2011) provided additional evidence for an association between the medial temporal lobe and spontaneous retrieval. Using structural MRI, they compared the integrity of regions of the medial temporal lobe to the ability to spontaneously retrieve prospective memories. They found a robust association between spontaneous-retrieval-dependent prospective memory performance and the structural volume of the medial temporal lobe (particularly the hippocampal subregion). Therefore, both the anterior prefrontal cortex and the medial temporal lobe are critical for supporting prospective memory.

Conditions Associated with Impaired Prospective Memory

Everyone experiences prospective memory failures, but some individuals appear to have worse prospective memory than others, and researchers have attempted to understand the underlying conditions that can lead to prospective memory impairments. Many studies have now been conducted on prospective memory in special populations that are at risk for having impairments in their anterior prefrontal cortex or hippocampal regions (i.e., the neural structures implicated in supporting prospective memory).

Substance Abuse

3,4-Methylenedioxymethamphetamine (MDMA) (Ecstasy)

Substance abuse, including the misuse or overuse of illegal drugs and alcohol, has long been known to affect neural and cognitive functioning. MDMA ('Ecstasy') use, for example, is linked to hippocampal and prefrontal cortex abnormalities (Cowan, 2007), and therefore one might anticipate MDMA users to demonstrate prospective memory impairments. Indeed, Rendell et al. (2007) found that MDMA users – even relatively infrequent users – show worse event-based and time-based prospective memory performance than nonusers.

Cannabis (Marijuana)

A second substance that is illegal in most countries and is commonly implicated in hippocampal impairments is cannabis (marijuana). Large-scale studies have found more frequent reports of everyday prospective memory failures in cannabis users than in nonusers (e.g., Cuttler et al., 2012). In addition, Montgomery et al. (2012) found that cannabis users performed much more poorly on naturalistic event-based tasks (e.g., remembering to turn on a coffee machine when a meeting begins) than nonusers, and that the impairments were exacerbated with higher frequency and doses of cannabis use.

Alcohol

Beyond illegal substances, other drugs such as alcohol have been linked to prospective memory impairments. For example, college-aged adults show more failures on time-based and event-based prospective memory tasks while intoxicated, even with relatively modest doses in which the participants do not subjectively perceive themselves to be intoxicated (Montgomery et al., 2011). Chronic alcohol abuse, which has been linked to impairments in hippocampal and prefrontal cortex functioning, may also have detrimental effects on prospective memory such that prospective memory functioning is impaired even when the individual is not intoxicated. Consistent with this idea, Heffernan et al. (2002) found that reported prospective memory failures were more frequent in chronic heavy alcohol users (i.e., individuals who ingest 30–60 units of alcohol per week for at least the last 5 years) than in low-dose/alcohol-free control individuals. The severity of chronic alcohol abuse may also be linked to prospective memory impairments. Korsakoff's Syndrome, which typically results from chronic alcohol abuse, is associated with profound frontal lobe impairments. Such frontal lobe impairments may explain why patients with Korsakoff's syndrome perform even worse than heavy users of alcohol on prospective memory tasks that rely on effortful monitoring (Brunfaut et al., 2000).

Neurodegenerative Diseases

Because prospective memory is critical for supporting health and for sustaining independent living (e.g., remembering to take medication, attending physician appointments, etc.) researchers have evaluated whether prospective memory is impaired in patient populations (Pirogovsky et al., 2012). Prospective memory impairments have been observed in several special populations including patients with schizophrenia, multiple sclerosis, attention-deficit disorder, AIDS due to human immunodeficiency virus (HIV) infection, and hypertension. However, the greatest amount of research has focused on prospective memory impairments in Alzheimer's disease and Parkinson's disease (see Figures 3 and 4,

Figure 4 Parkinson's disease is associated with declines in nonfocal prospective memory (monitoring) but not focal prospective memory (spontaneous retrieval). This figure was adapted from Foster, E.R., McDaniel, M.A., Repovš, G., Hershey, T., 2009. Prospective memory in Parkinson disease across laboratory and self-reported everyday performance. Neuropsychology 23, 347. The difference between this study and the McDaniel et al. (2011) study in healthy older adult nonfocal prospective memory performance relates to changes in some experimental features.

for a neurological condition by prospective memory task dissociation).

Alzheimer's Disease

Alzheimer's disease, which is known for its impact on the hippocampus as well as other neural structures (Buckner, 2004), has been widely diagnosed based on poor retrospective memory functioning. However, one Memory Clinic reported that 40% of their patients believed their primary memory issues to be related to remembering to perform delayed intentions (i.e., prospective memory; Kliegel and Martin, 2003). Consistent with patients' reported experience, several studies using objective measures of prospective memory have reported profound prospective memory impairments in Alzheimer's disease patients (Figure 3). Though retrospective memory failures (i.e., not remembering the prospective memory instructions) can partially explain prospective memory failures in this population, prospective memory deficits are observed even after controlling for retrospective memory deficits (e.g., McDaniel et al., 2011). Researchers have recommended that prospective memory tests be used alongside retrospective memory tests for the early detection of Alzheimer's disease (Duchek et al., 2006).

Parkinson's Disease

Prospective memory functioning has also been studied in Parkinson's disease patients. Parkinson's disease is typically known for its motor symptoms (e.g., bradykinesia, tremor, etc.), which are caused by the death of substantia nigra dopaminergic cells, but this disease has also been associated with cognitive impairments due to impaired frontal lobe functioning. Prospective memory impairments are robust in Parkinson's disease patients, and as illustrated in Figure 4, these deficits are more likely to be observed during prospective memory tests that rely on monitoring (nonfocal prospective memory) than those that rely on spontaneous retrieval (focal prospective memory; Foster et al., 2009; Kliegel et al., 2011). Some prospective memory impairments in Parkinson's disease may be partially reduced by administration of dopaminergic medication, which benefits frontal lobe functioning (Costa et al., 2008).

Normal Aging

One of the most common topics of research on memory concerns the evaluation of how memory changes with normal aging. The field of prospective memory has been no different. The effect of aging on prospective memory was one of the earliest questions in the field (e.g., Einstein and McDaniel, 1990), and aging has remained such a focus of the field that there are now multiple metaanalyses published on the topic (e.g., Henry et al., 2004; Kliegel et al., 2008). Though early research suggested that prospective memory is spared in normal aging, subsequent research suggests that this is not always the case. In both time-based and event-based laboratory prospective memory tasks, younger adults often outperform older adults. Age differences emerge especially when the laboratory prospective memory task challenges effortful monitoring processes. Such results might be attributable to the neurophysiological changes observed in the anterior prefrontal cortex with increasing age (McDaniel and Einstein, 2011).

Age differences in prospective memory are particularly pronounced in situations when an intention is successfully retrieved but the individual must postpone executing the intention. For example, an older adult might retrieve the intention to take medication but then postpone this intention in order to answer a ringing telephone; the question is whether the older adult still remembers to take the medication after answering the phone. Einstein et al. (2000) captured this prospective memory challenge in the laboratory using the delay-execute paradigm. As in the typical prospective memory laboratory paradigm, participants are told to perform a prospective memory action (e.g., press *Q*) in response to an environmental cue (e.g., the word *coffee*). However, participants must delay executing the prospective memory response for 5–15 s following the environmental cue. The results are demonstrated in Figure 5. Relative to a baseline condition in which the prospective memory response could be executed immediately, younger adults demonstrated minimal declines in prospective memory performance when they had to temporarily delay intention execution. Older adults, on the other hand, demonstrated dramatic declines in prospective memory performance, even with a 5-second delay interval (McDaniel et al., 2003). Therefore, interrupting the ability to immediately execute a prospective memory intention might be one of the most important factors that lead to prospective memory impairments in older adults.

Though age differences are often observed in laboratory prospective memory tasks, older adults commonly perform as well as, if not better than, younger adults in naturalistic prospective memory studies. The typical explanation for this age – prospective memory paradox (Rendell and Thomson, 1999) – is that in naturalistic settings older adults more often rely on external cues, or even on strategies such as reminders and avoiding interruptions, to bolster their prospective memory performance. The section on Improving Prospective

Figure 5 Results of the delay-execute paradigm. If an intention must be maintained in consciousness for 5 s prior to execution then prospective memory performance will drop dramatically in older adults but not in younger adults. The figure, and the phrase "do it or lose it" are adapted from McDaniel, M.A., Einstein, G.O., Stout, A.C., Morgan, Z., 2003. Aging and maintaining intentions over delays: do it or lose it. Psychology and Aging 18, 823 (Experiments 1 and 2b).

Memory elaborates on the approaches that have been found to be most viable for improving prospective remembering.

Improving Prospective Memory

Prospective memory failures can be embarrassing, such as forgetting to bring to class a reading assignment (perhaps even one on prospective memory) or failing to silence your phone before class and receiving a call. Failures in prospective memory can also be detrimental to health (e.g., failing to remember to take medication), and in extreme cases, they can even be fatal (e.g., a pilot who fails to remember to set the flaps during flight landing). Therefore, it is in every individual's best interest to know how to improve prospective memory.

Avoiding Interruptions

One line of research has focused on avoiding interruptions (cf deficits seen in Figure 5; Einstein et al., 2000). In the workplace environment, and especially healthcare environments such as the intensive care unit, nurses are constantly interrupted while attempting to perform prospective memory intentions (e.g., administering medication, recording vital signs). Grundgeiger et al. (2010) found that avoiding interruptions by insisting on completing an intention prior to focusing on the interrupting task is an optimal strategy for reducing prospective memory errors in healthcare.

Implementation Intention Encoding

Another line of research has attempted to boost prospective remembering at the encoding stage. Gollwitzer (1999) noted that people typically encode intentions in a very general manner (e.g., 'I need to call my mother'), and that general intentions are likely to go unfulfilled. The solution, referred to as implementation intention encoding (Gollwitzer, 1999), involves specifying a cue for when the intention should be executed (e.g., "When I finish my calculus class at 2 p.m., then I will call my mother") while visualizing performing that intention in one's mind. Benefits of implementation intention encoding on subsequent prospective memory performance have been demonstrated in several laboratory experiments (e.g., McDaniel et al., 2008). Furthermore, implementation intention encoding has produced benefits for real-world prospective memory intentions such as remembering to monitor blood glucose levels (Liu and Park, 2004), remembering to get an influenza vaccination (Milkman et al., 2011), and remembering to take Vitamin C supplements (Sheeran and Orbell, 1999).

Reminders and Smartphone Technology

A third line of research that focuses on improving prospective memory aims to remove the demanding cognitive components from prospective memory tasks. For example, using sticky notes (e.g., 'Go to the grocery store!') removes the 'memory' from 'prospective memory.' With advances in digital technology, reminders may be even more effective. Smartphones that are kept near their user and produce a sound or vibration concomitant with written text have the potential to act as reminders of prospective memory intentions. The benefit of smartphone applications and other digital reminder systems (e.g., Google calendar) for facilitating prospective remembering in everyday settings has been observed even in patients with traumatic brain injury and severe amnesia (McDonald et al., 2011; Svoboda and Richards, 2009). Such results provide promise for the future of improving prospective memory functioning in patient populations, the workplace, and everyday life.

Abstract

Prostitution is a gendered, sexualized, and racialized labor system, one that typically involves the exchange of sexual services for money, goods, or other benefits. Sex work encompasses different types of intimate arrangements that blur the boundaries between erotic, emotional, and economic labor. Sex work is also part of an industry and commercial market that is global in reach and diverse in its spatial, legal, and occupational organization. This article investigates the multifaceted dimensions of prostitution and sex work in a twenty-first century context. In it, we explore how sex work as an intimate form of labor has evolved alongside other social and economic shifts, such as technology innovations and the growth of neoliberal globalization. We further examine the divergent contexts in which sex work takes place, how scholars have differentially approached its study and how states' employment of disparate regulatory strategies and antiprostitution policies have, in many instances, stigmatized sex workers.

Prostitution, Sex Work, and the Commodification of Sexual Activity

Accounting for twenty-first century manifestations of prostitution or 'sex work' – a term used interchangeably throughout this article – is a cumbersome exercise. This is because prostitution is neither a universal empirical phenomenon, nor does it express streamlined meanings or definitions (Ditmore, 2006). To examine prostitution within a social science framework invites consideration of the divergent environments in which it takes place. It further demands attention to the varied ways in which sex workers' gender, race, class, sexual identity, and citizenship status intersect in shaping their experiences of sexual labor and the uneven degrees of oppression, discrimination, and criminalization they may face (Kempadoo, 2001; Kempadoo and Doezema, 1998; Kempadoo et al., 2005; Vanwesenbeeck, 2001; Wahab, 2005; Weitzer, 2005).

Broadly defined, prostitution is a gendered, sexualized, and racialized labor and economic arrangement that commonly involves the exchange of sexual services for money or goods (Peppet, 2013: 10, Showden and Majic, 2014: xiii). Sex work may also encompass a range of intimate labors (Constable, 2009: 50) such as stripping, bar work, massage, camming, tourist encounters, and "the girlfriend experience" (Bernstein, 2007) – among others – and include more than "direct sex-for-money exchanges" (Hoang, 2010: 256). This article focuses on physical acts of sexual intimacy that are traded in some form. Although erotic dance and porn are commonly included under the umbrella of sexual labor, we exclude them here for space and specificity.

The examples we discuss here aim to illuminate key themes under discussion; however, there is undoubtedly variance across national contexts that were not explored in depth. Due to space constraints, certain topics are also left unexamined, including research on customers, in-depth country histories, specific workplace practices, the experiences of transgender and male sex workers, sex-trade involved youth, and the role that market mediators, managers and 'pimps' play in facilitating sexual labor.

Precise estimates of the scope and scale of prostitution are difficult to track (Brents and Hausbeck, 2010: 13; Weitzer, 2007; Vanwesenbeeck, 2001). Complicating assessments of prostitution further still are frequent scholarly and policy references to data based on imprecise and inflated numbers (Wagenaar et al., 2013: 26, 87). Sometimes framed under the umbrella of a "global sex trade" (Kempadoo, 2001), prostitution and its attendant markets are invariably localized even while its local emergence is shaped by migration patterns, neoliberal globalization (Bernstein, 2007; Chin, 2013), and domestic and intergovernmental policies. The state plays a central role in how individuals experience sex work and any corresponding violence and stigma they encounter (Bernstein and Schaffner, 2005; Kelly, 2008; Sanders et al., 2009).

Legal, Spatial, and Sociotechnical Dimensions of Sex Work

Prior research has examined workers' motivations for entering sex work (Hardy et al., 2010; Abel et al., 2010; Sanders, 2005; Katsulis, 2010) and explored the physical, aesthetic, and emotional dynamics that accompany sexual labor (Brents and Jackson, 2013; Brewis and Linstead, 2000; Chapkis, 1997; Sanders, 2005). These studies begin to offer classifications of varying sex industries that include everything from brothels to independent escort services. They also consider how place, space and class shape intimate exchanges, suggesting that the meaning, terms, and empirical reality of prostitution is contingent and contextually specific.

Scholars have also focused on geographies of sex work (Hubbard, 1999, 2013; Bernstein, 2007; Katsulis, 2010; Kingston, 2014; Wonders and Michaloski, 2001), interrogating its spatial and legal dimensions. Sex work may take place in 'offline' outdoor and street-based settings or indoor venues

such as clubs, hotels, brothels, and residential areas. Whether focused on rural or urban settings or the specific locations where clients are secured and exchanges occur, the spatial organization of commercial sex is significant in that it impacts workers' experiences of sexual labor and additionally shapes community responses to it (Hubbard, 2001, 2004).

The growth and expanded use of online, mobile, and network technologies signals that sex work is increasingly mediated by and through technology. For instance, mobile phones and online classified ad sites enable sex workers and third party actors to advertise sexual services to prospective customers at low costs (Peppet, 2013). Technologies also create new niche markets and expand the possibilities for different kinds of commodified sexual encounters. Camming, for example, involves models performing web-based sex shows (Richtel, 2013) that are accessible by viewers from all over the globe. On one hand, this may give adult consensual sex workers or those who coordinate their services the ability to screen potential clients (Peppet, 2013: 2008–2010) and wield greater control over their working environments. On the other hand, online ad postings and mobile communication create new mechanisms for law enforcement to surveil the online, mobile, and social media activities of voluntary sex workers and as well as individuals deemed at risk for forced prostitution and "sex trafficking." (Musto and boyd, 2014). Such surveillance may lead to heightened criminalization and the entrapment of immigrant and domestic sex workers alike, thus underscoring that though technology stands to reconfigure how sex work is organized and facilitated, sexual labor remains highly stigmatized and closely monitored by the state.

Countries today are grappling with new and different approaches to regulating the sale of sex (Dewey and Kelly, 2011; Goodyear and Weitzer, 2011; Kempadoo et al., 2005; Weitzer, 2012). In addition to controlling the sale of sex itself, policies focused on other phenomena such as immigration, public health, morality, and sex trafficking also impact how prostitution is regulated.

Goodyear and Weitzer (2011) argue that government regulation falls into two general categories: "(1) intensified *criminalization* designed to eradicate it; and (2) *liberalization* based on principles of harm reduction, labor rights, and civil regulation of commerce" (16, italics in original). The Netherlands, a country where prostitution is legally permitted has introduced municipally orchestrated licensing schemes (Outshoorn, 2014: 174). Canada also regulates sex work (Van der Meulen et al., 2013), but through a combination of licensing requirements and criminalization (Auger, 2014: 101). Other countries have regulated prostitution through different forms of criminalization. In 1999, the Swedish government moved to criminalize the purchase of sex (Levy and Jakobsson, 2014: 5). Proponents of the Nordic 'End Demand' strategy viewed it as a way to reduce prostitution by criminalizing the clients of sex workers (Levy and Jakobsson, 2014: 7). While the law aimed to abolish prostitution by reducing demand, scholars find that it did not accomplish this goal but instead moved sex work from visible street locations to indoor locations or to "neighboring countries" (Chu and Glass, 2013: 105, Levy and Jakobbson, 2014). Though some scholars find that sex workers' safety has been compromised following the law's passage (Levy and Jakobbson, 2014), the 'Swedish Model,' as it is known, has become popular among some policy-makers, activists, and academics, evidenced by its adoption or desired adoption across countries in Europe, under review in Canada, and certain states in the United States.

In the United States, both the sale and purchase of sex is criminalized – save rural brothels in the state of Nevada (Brents et al., 2010). Efforts to 'clean up' and manage street-based prostitution through law enforcement antiprostitution raids have been extended indoors and online (Bernstein, 2007; Musto and boyd, 2014) and expanded as a response to concerns about sex trafficking. U.S. sex worker rights organizers have challenged criminalization and agitated for legal and cultural change (Chateauvert, 2014; Jenness, 1990, 1993; Majic, 2013; Showden and Majic, 2014; Weitzer, 1991). In New Zealand, prostitution was decriminalized in 2003. The New Zealand Prostitutes' Collective worked with a range of state and key actors to facilitate the change in law. Though the impact of decriminalization is still being studied, some research indicates that it has led to better health and other outcomes for many workers, though some – youth, for example – continue to struggle to access services and work safely (Abel et al., 2010).

Irrespective of whether countries criminalize, decriminalize, or legalize commercial sex, it is an industry that is highly, albeit unevenly, regulated. Moreover, though countries may adopt what appear to be different approaches to its regulation, the effects of laws and the kinds of spatial control sex workers experience bear some similarity. Certain broad observations can be made. First, policies aimed at reducing the demand of prostitution, or removing street-based prostitution from public view, may not reduce it per se but shift it to off-street and online locations. Second, cultural, religious, and societal expectations that sex workers are 'fallen women' to be pitied, or exploited victims in need of saving (Doezema, 2001), have exacerbated the stigma associated with sex work even in countries where prostitution is legalized or decriminalized. Third, the magnitude with which prostitution is regulated and policed highlights how the criminal justice system is used as a form of social control over poor women and other marginalized and vulnerable populations such as undocumented immigrants (Chapkis, 2003; Ditmore, 2005), youth of color, and gender nonconforming individuals. Fourth, a disconnect commonly exists between how laws are written and how they are implemented on the ground, which can promote 'unintended consequences' (Wagenaar et al., 2013: 88) that detrimentally impact sex workers. Finally, widespread moral panics surrounding "sex trafficking" (Weitzer, 2007; Mahdavi, 2014) in diverse national contexts have shored up antiprostitution sentiments where prostitutes are seen as victims in need of protection – yet many sex workers, in reality, are treated as criminal offenders subject to carceral intervention (Ditmore, 2009; Bernstein, 2010; Musto, 2013). Here it is not just the state that has sought to intervene on the behalf of sex workers. Transnational faith-based efforts to abolish prostitution have aligned different groups like conservative evangelical Christians with radical, antiprostitution-minded feminists (Bernstein, 2007). These interventions have subjected sex workers to heightened religious and

humanitarian oversight (Bernstein, 2010) sometimes by outside transnational actors including global governance institutions like the United Nations, International Labor Organization, and multinational lending institutions like the International Monetary Fund when punishments for noncompliance to antitrafficking efforts are accompanied by international sanctions (Shih, 2014b; Mahdavi, 2014). They have also brought nonstate sponsored activist campaigns, shelters, and alternative employment schemes to countries with disparate histories for managing commercial sex (Shih, 2013).

Sex Work as Violence, Exploitation, Labor, and Choice

Disagreement exists as to whether sex workers wield control over the conditions and environments in which they operate. For example, one can find in the literature hotly contested debates and blurred lines between voluntary consensual sex work and forced prostitution (e.g., sex trafficking) (see Jeffreys, 2009; Raymond, 2004 for concerns about the sale of sex as violence against women; for critiques see O'Connell Davidson, 2006; Weitzer, 2007). Scholars routinely observe that sex work and sex trafficking are empirically distinct phenomena. Yet since the 1990s, sustained attention and persistent contestation about prostitution have resuscitated longstanding feminist concerns about power, sex, gender, oppression, violence, and the state and amplified international and domestic policy attention to sex trafficking.

The terms of these debates and the discursive tensions they have produced are widely documented (Chuang, 2010; Limoncelli, 2009; Anderson and Andrijasevic, 2008; Agustín, 2007; Saunders, 2005; Parreñas, 2011). Some activists have expressed concern that sex workers and trafficking victims have been inadequately represented within feminist discussions and that sex workers' voices have been discounted. Even in light of these valuable critiques, a brief discussion of feminist theoretical treatment of prostitution is warranted, if only to signal how competing feminist orientations to the topic continue to frame mainstream discussions and focus policy considerations.

For over a half a century, feminists across the globe have vigorously debated the political salience of prostitution, particularly as it relates to the experiences of women. As Anderson and Andrijasevic (2008) note, 'abolitionist feminists' view prostitution as akin to 'sexual slavery,' an extension of 'patriarchal domination over female sexuality,' and understand it as a 'gender crime' (Anderson and Andrijasevic, 2008: 139). Comparing prostitution to a gender crime has gained traction in many countries following the UN's adoption of the Palermo Protocol in 2000, an instrument that frames antitrafficking efforts through the lens of controlling crime (Anderson and Andrijasevic, 2008: 136). Abolitionist ideologies lend support to criminal justice antiprostitution efforts, what Bernstein critiques as a form of 'carceral feminism' (Bernstein, 2010). This is a feminist inspired antitrafficking approach that relies on the state to protect prospective sex trafficked victims from (perceived) threats and violence, resulting in a 'rescue industry' (Agustín, 2007) of government agencies, nonprofits, and NGOs whose funding and existence relies on identifying, rescuing, and rehabilitating sex trafficking victims/survivors. Bernstein's (2010) observations about the fusion of abolitionist sentiments with criminal justice efforts demonstrate how abolitionist ideologies have been bolstered by heightened attention to sex trafficking globally.

Scholars have documented the problems with the abolitionist approach. In a U.S. context, antiporn crusaders of the 1980s arguably found new cause in antitrafficking efforts that began in the late 1990s. In so doing, they abandoned broader sociolegal concerns about migration, global economic inequality, and labor rights across a range of informal labors (e.g., domestic work, construction) in favor of a narrow focus on sex trafficking of women and girls (Agustín, 2005; Ditmore, 2005; Doezema, 2002, 2010; Kempadoo et al., 2005; Sanghera, 2005; Schaeffer-Grabiel, 2010). The violence against women framework thus neglects to grapple with histories of racism, colonialism, imperialism, and the global economic conditions that shape twenty-first century prostitution (Kempadoo, 2001: 34; 37–38). The abolitionist feminist perspective also blunts the development of effective strategies to secure sex workers' health, occupational safety, and human rights (Kempadoo, 2001).

Others have instead adopted a 'sex workers' rights' based approach to the topic (Anderson and Andrijasevic, 2008: 139; Delacoste and Alexander, 1998; Ditmore et al., 2010). Arguing against the premise that all prostitution is coerced and highlighting the problematic conflation of prostitution with violence against women (Saunders, 2005), prorights feminists suggest that sex work is a form of labor (Chateuavert, 2014: 193), and that people can and do voluntarily choose to engage in prostitution, not only amid constrained economic circumstances but as a well-informed 'advancement strategy' (Brennan, 2002; as cited in Saunders, 2005: 353). Prorights and transnational feminists draw attention to structural factors (Hoang, 2010) that render women in general and women of color and *transwomen* in particular vulnerable to economic precarity.

Disagreement as to whether voluntary prostitution is possible (Dworkin, 2004; Farley and Barkan, 1998; Jeffreys, 2009; Raymond, 2004) or whether the regulation of sex work contributes to sex trafficking are not merely philosophical nor are these debates exclusive to feminists. Rather, these debates contribute to questions about policy and raise a number of critical questions: Should countries decriminalize or legalize the sale of sex to best protect workers and prevent trafficking? Or should prostitution be further prosecuted and penalized? What kinds of laws, policies, and activities support sex workers and prevent against coercion, exploitation, and workplace abuses within the sex trade? What experiences are privileged by the violence against women framework and what experiences and circumstances does it leave unacknowledged? Levy and Jakobsson (2014) find that laws that criminalize the purchase of sex in Sweden advance a narrow rendering of prostitution as violence against women (2014: 3). This framing ignores transgender and men's experiences, in addition to ignoring the voices of women within the sex trade and arguably reflects more broadly held antiprostitution sentiments that do not complicate the gender essentialist, heteronormative, and transphobic assumptions on which they are built. Debates surrounding prostitution ultimately hinge on how different interest groups, whether feminists, sex workers, public health

officials, legal experts, economists, and policymakers differentially define harm, violence, and protection and the kinds of laws, policies, and activities deemed best equipped to support sex workers and prevent against coercion, exploitation, and workplace abuses within the sex trade.

Sex Work and the Nation State

A discussion of sex work also invites consideration of the structural conditions and geopolitical context in which different kinds of sexual labor manifest. This kind of analysis proves essential to understanding the disparate and uneven experiences of individuals who engage in sexual commerce in a late modern, globalized landscape. Global economic restructuring, income inequality, international sex tourism (Hall and Ryan, 2001; Ryan, 2000; Wonders and Michalowski, 2001), and the unprecedented scale of internal and international migration (Agustín, 2003) situate prostitution at the nexus of global capital, mobility, and the nation state.

Prostitution is sometimes framed within the context of state-sponsored decision-making and corporate expansion, such as the state-sponsored brothels in the capital city of Chiapas, Mexico (Kelly, 2008). Others trace the emergence of contemporary forms of prostitution in South World cities to free trade zones (Kempadoo, 2001), areas occupied by military and peacekeeping forces (Cheng, 2011), "global cities" (Sassen, 2004, Chin, 2013: 9) and sex tourism as a strategy of economic development (Padilla, 2007; O'Connell Davidson and Sánchez Taylor, 2005; Da Silva and Blanchette, 2009). Sex work is not wholly dissimilar from other low wage and informal work opportunities migrants may seek. However, the constraints and stigma migrant sex workers experience are distinct and typically more pronounced both because of their citizenship status and as a result of law enforcement oversight (Chapkis, 2003; Agustín, 2005; Luibhéid, 2002).

Laws that make prostitution illegal often contradict economic development policies that indiscriminately seek profit off the bodies of working class people. For instance, while prostitution is illegal in Thailand, the government has supported unbridled tourist-industry expansion as a primary engine of economic development. Following the arrival of tens of thousands of American military service to Thailand for Rest and Recreation (R and R) during the Indochina Wars, Thailand's sex tourist economy became the largest in the world. In the present day, sex tourists from across the globe – including a large number of clients from within Thailand and across Asia – arrive in Thai cities seeking different forms of intimate exchange, including diverse companionship arrangements (Skrobanek et al., 1997; Manderson and Jolly, 1997; Jeffery, 2002; Wilson, 2004; Empower, 2011). For instance, in research on professional girlfriends in Cambodia, Hoefinger describes these unique relationships as 'transactional partnerships; (Hoefinger, 2013). The diverse clientele of sex workers has also been specifically addressed by Hoang (2014), whose research in Vietnam suggests that the aesthetic desires of different male clients illuminate new sex worker strategies for embodiment vis-à-vis race, nation, and modernity. The specificities of sexual commerce and the constellation of relationships that emerge from such arrangements suggest that the moral panics around sex tourism are yet another instance of over-inflated vigilance and stigmatization of sex work.

Everywhere from South Korea, China, Mexico, Brazil, France, Italy, Japan, to the U.S., among other destinations of migration, global panics and antisex trafficking discourses and politics have fostered a migration and policy environment in which the depiction of sex work as violence overshadows highly exploitative manual labor conditions in the service and manufacturing sectors. For instance, Shih (2013; 2014a) work on vocational training programs for former sex workers in Beijing and Bangkok argues that the typical gendered rehabilitative labors of sewing, jewelry making, and garment work offer nonautonomous and exploitative working conditions of manual labor (Shih, 2014b). Plambech's (2014) critique of the larger cyclical repatriation/deportation industry for Nigerian sex workers to Italy reveals the undeniably punitive effects of global sex worker rescue efforts (Plambech, 2014). Exclusive attention to rescuing and rehabilitating sex workers overshadows attention toward improving safety and accountability within sex work. Rather than rescue, sex worker rights organizations have asked for increased attention to violence, protection against police violence, greater employer accountability, secure payment mechanisms, and the right to unionize.

In May 2014, months before the launch of the World Cup in several cities throughout Brazil, local government and police participated in a sanitization campaign that illegally arrested over 100 Rio-based sex workers and subjected them to numerous rights violations. Earlier that year, Putin's "security ring of steel" around the Olympic town of Sochi conducted similar operations, reminding observers of similar policies to ban prostitutes from Moscow during the 1980 Olympics (Vostocable, 2014). Similar policies existed just prior to the 2008 Beijing Olympics: mass-scale 'deportations' of rural migrant sex workers to their hometowns (Nyiri, 2010). The links between large-scale internationally televised sporting events and prostitution (Hennig et al., 2007, Richter et al., 2010) have also been highlighted by a recent spate of reporting on the link between sex trafficking and the U.S. Super Bowl (Peterson, 2011). Yet studies find that sporting events like the World Cup do not lead to increased sex trafficking but rather increased police attention (Gould, 2010; Richter et al., 2010; Tavella, 2007)

Sex Workers as Knowledge and Cultural Producers

Sex workers have led local and transnational efforts to advocate for sex workers' health, occupational safety, and human rights. Across the globe, sex workers demand the right to work safely and free from violence, and they agitate for basic human rights to work, family, and citizenship. Some engage in research, such as the online *Research for Sex Work* journal of the Global Network of Sex Work Projects that has produced scholarship since 1998. Works like *Sex Work: Writing by Women in the Sex Industry* (Delacoste and Alexander, 1998), *Playing the Whore: The Work of Sex Work* (Gira Grant, 2014), and *Hos, Hookers, Call Girls, and Rent Boys: Professionals Writing on Life, Love, Money, and Sex* (Sterry and Martin, 2009) are U.S.-based

cultural interventions into the narratives told about sex workers by academics and political stakeholders.

In Thailand, the EMPOWER Foundation, founded in 1984, is the nation's earliest sex worker rights organization, staffed by and in service of sex workers. It provides a variety of outreach, research, and advocacy programs including language training in English and Thai, rights awareness, and health education, and has implemented the nation's first sex worker owned and operated bar, *The Can-Do Bar*, which operates in compliance with local labor laws (Empower, 2012; Kinney, 2014). In 2012, Empower joined several sex worker rights organizations throughout the Southeast Asian region to found 'SWASEAN' (Sex Workers of ASEAN), building on the Association of Southeast Asian Nations (ASEAN), the primary political and economic agreement in the region. SWASEAN has organized the exhibition of sex worker-produced works of art, ranging from films, music, visual and performance art, in different venues throughout the region. Alongside their cultural work, Empower frequently publishes their own books and manuals, and in 2012 published a landmark research report, 'Hit and Run,' that provided extensive documentation of how the antihuman trafficking movement has inflicted harm on sex workers (Empower, 2012).

Several well-known sex worker rights organizations have sought to make a large-scale impact, often integrating local outreach and direct services to sex workers with national global research, advocacy and policy making agendas. In India, the Durbar Mahila Samanwaya Committee (DMSC), founded in 1992, is a collective of over 65 000 sex workers who organize and work in the Sonagachi district in Kolkata. DMSC leads 'community-based structural interventions (CBSI),' pioneering one of the largest community development models of interventions to HIV/AIDS, forging a "multisectoral response to structural drivers of HIV/AIDS" (Swendeman, 2013). The New Zealand Prostitutes Collective developed a draft that became the Prostitution Reform Bill of 2003, effectively decriminalizing sexual labor in that country. Arguably these achievements are due to the collaboration between sex workers and allies from public health sectors and policymakers, as well as other interested agencies and organizations (Abel et al., 2010).

While sex workers have incorporated new and innovative strategies for cultural activism, these perspectives are still often marginalized by mainstream, sensationalized portrayals of sex as an 'iconic, unequivocal, and perpetual human rights violation' (Shah, 2013). These accounts – a genre that Carole Vance calls a 'melomentary' (Vance, 2012) – includes television, film, journalistic and literature accounts and represent ripe artifacts of the socially constructed – and often contested – terrains of sex work.

Concluding Thoughts

In this late modern, postindustrial landscape in which sexual commerce is organized, the boundaries between erotic, emotional, and economic exchanges are invariably blurred (Bernstein, 2007; Sanders, 2005; Zelizer, 2005) and individuals' motivations and experiences with it wide-ranging. Scholarly debates surrounding prostitution continue to be fiercely waged, particularly as concerns about sex trafficking have fostered antiprostitution responses. This article offers snapshots of some of the broad terms, discursive tensions, and overarching questions that foreground contemporary scholarly treatment of prostitution and sex work. As prostitution and sex work continue to evolve, future research by sex workers and scholars is needed to map the salience of these changes and gauge its impact on the people most directly impacted.

Prototype Theory in Linguistics

Abstract

Prototype theory, as developed by Rosch, has had repercussions in two main areas of linguistics: lexical semantics and syntax. Word meanings are the names of categories, and the meanings of many words display characteristic prototype effects (fuzziness of category boundaries, degrees of neo-Kantians of category members). Further areas of application have been semantic change and the structure of polysemy networks. The prototype approach does, however, encounter problems in connection with theories of semantic compositionality. Linguistic constructs, such as syntactic and lexical categories, also display prototype effects. The application of prototype theory to the study of parts of speech and syntactic constructions has been especially fruitful.

Prototype theory, as developed by Rosch, has had repercussions in two main areas of linguistics: lexical semantics and syntax. Word meanings are the names of categories, and the meanings of many words display characteristic prototype effects (fuzziness of category boundaries, degrees of representativity of category members). Further areas of application have been semantic change and the structure of polysemy networks. The prototype approach does, however, encounter problems in connection with theories of semantic compositionality. Linguistic constructs, such as syntactic and lexical categories, also display prototype effects. The application of prototype theory to the study of parts of speech and syntactic constructions has been especially fruitful.

Prototype theory is a theory of categorization. Categorization is a central issue in linguistics, for several reasons. In the first place, words can be regarded as names for categories, and using a word involves an act of categorization (Labov, 1973). In stating that The cup is in the saucer, a speaker is categorizing the figure object as a 'cup,' rather than as a mug, bowl, vase, or other kind of object; the reference object is being categorized as a 'saucer,' not as a dish or a plate; while the location of the cup vis-à-vis the saucer is being categorized as an 'in'-relationship, rather than as an 'on'-relationship, or whatever. Knowing these words involves knowing how to apply the words appropriately to entities that fall within the categories that they designate.

There is another way in which categorization impinges on linguistic theory. The moment one pursues even the most elementary linguistic analysis, language itself becomes an object of categorization. Like any intellectual discipline, linguistics requires its practitioners to set up categories for the description of the object of study. In any linguistic description, one will encounter such entities as words and morphemes, phrases and clauses, nouns and verbs, subjects and objects, clitics and particles, phonemes and allophones. 'Doing linguistics' consists, in large measure, in setting up categories such as these, defining them, studying their properties and interrelationships, working out criteria for determining their membership, and applying them to the data at hand. The ontological status of the categories themselves may also become an issue. Where do categories such as 'noun' and 'verb' come from? Are they inherent in the object of study? Are they mere descriptive conveniences? Are they constructs of linguistic theory?

Two Approaches to Categorization

Two major approaches to categorization are the 'classical' approach and the 'prototype' approach. On the classical approach, a category is defined in terms of a set of necessary and sufficient conditions for category membership. The set of conditions specifies the essence, as it were, of the category. Any entity meeting all the conditions is, by definition, a member of the category; failure to meet any of the conditions excludes an entity from the category. On this view, category boundaries are discrete (an entity either is, or is not, a member), and the category lacks internal structure (all members are of equal status).

The simplicity of the classical view makes it intuitively appealing. A major problem is that many categories are simply not amenable to classical definition. What, for example, are the defining features of 'chair,' 'vegetable,' and 'love,' or, for that matter, of 'cup,' 'saucer,' and 'in'? In fact, classical categorization probably works best only for 'expert' categories, that is, categories that have been created and explicitly defined (in classical terms!) by experts, whether these be scientists, bureaucrats, administrators, or whoever. For most words of everyday speech, the classical theory is quite inappropriate.

On the prototype approach, a category is understood, primarily, in terms of its good examples. Entities are associated with the category to the extent that they resemble the good examples. Often, the boundary of a prototype category will be fuzzy – it might not be clear whether some entities belong in the category or not. Moreover, prototype categories have an internal structure, in that some entities count as more central members than others.

Prototype categorization came to the attention of linguists largely due to the work of the psychologist, Eleanor Rosch. In a series of experiments, summarized in Rosch (1978), it emerged that the meanings of several very ordinary words, such as bird, toy, vehicle, are structured around good examples. People readily agree that a robin is a better example of 'bird' than a penguin; they can determine the truth of A robin is a bird

faster than A penguin is a bird; when asked to name members of a category, they name more central examples before more marginal examples; and when drawing inferences about a category, people tend to draw on knowledge of central members, rather than on knowledge about the category as a whole. Rosch observed prototype effects both with 'natural kind' categories – that is, categories such as 'bird,' which are, as it were, given by nature – and with categories that are understood relative to human concerns, such as 'vehicle,' 'furniture,' and 'toy.'

Rosch's discoveries were eagerly taken up by linguists and extended by a wide range of linguistic data (Lakoff, 1987; Kleiber, 1990; Tsohatzidis, 1990; Geeraerts et al., 1994; Taylor, 1995). An especially fruitful application has been the study of semantic change (Geeraerts, 1997). The prototype notion has also been widely applied to the study of the categories of linguistic description (Langacker, 1987; Croft 1991).

Problems and Refinements

Despite its success in lexical semantics and elsewhere, prototype categorization raises a number of problems.

While not denying the reality of prototype effects, Fodor (1998) argues that concepts cannot be equated with prototypes. The fish prototype (a herring?) and the pet prototype (a poodle?) contribute nothing at all to the complex concept 'pet fish,' or to the prototype of 'pet fish' (a goldfish?). Generally, as a concept gets specified in greater detail, prototype effects not only shift, they also tend to get effaced. Consider the diminishing role of the 'nurse' prototype in one's understanding of nurse, male nurse, retired male nurse, etc. On the other hand, prototype effects show up even on categories that arguably are subject to classical definition, such as 'odd number.' Armstrong et al. (1983) report that subjects readily agreed that 3 was a better example of 'odd number' than 447, even though, obviously, 447 is no less of an odd number than 3.

On one interpretation of these findings, prototype effects are extrinsic to word meanings as such and arise only when a person applies a concept to the world. This view draws a distinction between the 'essence' of a category (the 'real' meaning of a word) and 'recognition procedures' invoked when speakers attempt to categorize things and eventualities in the world. On this view, the fuzziness of category boundaries results from the fact that eventualities in the world may not lend themselves to clear-cut categorization, even though the words of a language do have clear-cut meanings. Although it might not be clear whether a particular utterance counts as a 'lie,' the meaning of lie might nevertheless be clear-cut.

Degree of Membership versus Representativity

Before endorsing this exclusion of prototypes from word meaning proper, it is important to distinguish two aspects of prototype categories: fuzziness of category boundaries (a question of category membership) and degree of representativity within a category (a question of category structure).

It is uncontroversial that certain categories are inherently fuzzy, in that it is simply not possible to make a clean distinction between what goes into the category and what does not. This is the case with many adjectival concepts such as 'old,' 'tall,' and 'bald.' While there is little doubt what a (prototypical) bald head looks like, also what it means to be not bald, it would be futile to draw a boundary between 'bald' and 'not bald,' e.g., in terms of the number of hairs on a person's head.

However, prototype effects also show up on categories that arguably do have clear boundaries. Although turkeys might not be good examples of the bird category, they are birds nonetheless, albeit not very representative ones. Representativity, to be sure, can be understood in different ways – in terms of frequency of occurrence, cultural or environmental salience, or statistical averaging over category instances. Representative examples are typically invoked in default contexts. Given only the mention of 'a bird,' with no further specification, one would assume a representative example. People who wish they were a bird would surely be disappointed if they were transformed into a turkey! The internal structure of a category cannot reasonably be excluded from a person's knowledge of word meanings.

Prototypes and Background Knowledge

Categories, in order to be viable, need to be conceptually coherent (Murphy and Medin, 1985). A category is coherent to the extent that it is based on theories of how the world is, and how it links up with a person's encyclopedic knowledge. A category is not simply a conjunction of an ad hoc set of features, but the category has to make sense.

Lakoff (1987) discusses this aspect in terms of his notion of the idealized cognitive model (ICM). The concept 'bachelor' is understood against an ICM of marriage practices (which in turn is based in ICM's of sexuality, procreation, and family). One aspect of the ICM is the idea that each person, after reaching the 'marriageable age,' sooner or later marries. Within the ICM, bachelor may well be definable in classical-like terms, i.e., as 'unmarried,' 'adult,' and 'male.' Prototype effects arise, because the ICM may not fit the world perfectly. The Pope is not a good example of 'bachelor,' not because of uncertainties about whether the Pope is unmarried, adult, or male, but because Catholic clergy are outside the scope of the ICM.

Prototypes and Features

On the classical theory, categories are assembled, as it were, out of their features; the features preexist the category, are evaluated independently of the category, and must be simpler than the category they define. A prototype, in contrast, can be perceived holistically, as a gestalt; features are no longer the building blocks of categories; they emerge, as dimensions of similarity, through acquaintance with category members. It is unlikely that people construct their bird category through conjunction of features such as 'having feathers' and 'laying eggs'; knowledge of feathers and egg-laying emerges from acquaintance with birds, not vice versa. Likewise with linguistic categories. One might propose that ability to inflect for tense is a defining characteristic of verbs (for English, at least). Yet, the very notion of tense inflection rests on a prior acquaintance with members of the verb category.

Given this revised understanding of features, a feature-based view of prototype categories becomes possible through the

differential weighting of the features. Some features may be better cues to category membership than others; some features may be virtually indispensable; others are able to be overridden. The prototype will be a representation that maximizes feature weights; an entity exhibiting highly weighted features will automatically count as a category member; an entity exhibiting less highly weighted features might still count as a member, though a more marginal one. Moreover, it is possible for two entities to belong to a category, even though they have no category-specific features in common. The way also opens up for a reconciliation of classical and prototype categorization – a classical category is the limiting case of a prototype category, i.e., a category understood solely in terms of essential features.

Prototypes and Polysemy

It is useful to distinguish between the prototype structure of a concept and the polysemy structure of a word. There is a clear difference, in principle, between applying the word fruit to different kinds of fruit and the use of the word in such expressions as the fruit of his labors. The latter usage represents a semantic extension of the word, in a way that is different from the use of the word to refer, say, to olives.

Take the preposition over (Lakoff, 1987). Fly over the Atlantic, the lamp hanging over the table, put your hands over your face, come over here, there is water all over the floor, the party is over, do it over again – these exemplify different senses of the word, rather than more or less representative examples of one and the same sense. To the extent that these senses can be clearly individuated, it is possible to construct a network of sense relations, which links up the different senses according to their similarity. Such an array invites a prototype analysis, with one of the senses selected as central and the others radiating out from it.

There are, however, different criteria for selecting the central sense, and these do not always deliver the same result. On a diachronic perspective, the basic sense is the historically oldest one, from which the others have been derived over time. On a developmental perspective, the basic sense is the one that children acquire first. Alternatively, the descriptive linguist (or lexicographer) might select as basic the most frequent sense, or the one to which the others can be most economically related. The real question, however, concerns the speaker's mental organization of polysemy. Currently, this is a lively topic in polysemy research (Taylor, 1995).

Prototypes and Linguistic Categories

The prototype concept may be applied, not only to the study of word meanings, but to the very categories of linguistic description. Many linguistic concepts (including the very notion of 'language' and 'a language') turn out to have a prototype structure, in that they exhibit degrees of representativity, and often have fuzzy boundaries. Uncertainty as to what goes into a category and what does not pertains even to such basic notions as what constitutes a word (as opposed to a bound morpheme, clitic, or phrase), the part-of-speech categories (whether a particular item is a noun, verb, adjective, etc.), constituency (whether a particular string of words is a syntactic constituent), and syntactic relations (whether a particular constituent is a modifier or adjunct, the subject of a clause, or whatever).

Some linguistic theories propose to decide such issues by fiat. In practice, however, the linguist's strategy often reflects a prototype conception, even though this might not be explicitly acknowledged. When deciding the category status of a linguistic item, it is usual to apply a set of tests (Croft, 1991). The tests are set up on the basis of what, intuitively, count as good examples of the category in question, whereby each of the tests diagnoses a property typical of the good examples. An item that passes all the tests is ipso facto a member of the category; an item that fails the tests is not a member. Sometimes, an item passes only some of the tests; it will have to be regarded as a marginal example, or even as an item of uncertain status.

Consider the parts of speech, perhaps better called 'lexical categories' such as 'noun,' 'verb,' 'adjective,' 'preposition' (*see* Parts of Speech). These can be characterized either in semantic or in formal terms. Semantically, nouns prototypically designate categories of things, i.e., concrete, time-stable, spatially bounded objects (chain, cup, etc.); verbs designate events, involving rapid changes in state (explore, arrive); adjectives designate fairly stable properties of things (hot, young); while prepositions designate a relation, typically a spatial relation, between things (on, at). It is commonly agreed that lexical category cannot be reliably predicted from a word's semantics. In spite of their reference to rapid changes in state, explosion and arrival are nouns, just as good nouns, in fact, as chair and cup. This is because the words exhibit the full range of formal properties typical of the noun category, i.e., they pass all the syntactic tests for nounhood – they pluralize, they take the full range of determiners, they can be modified by an adjective, they can head a subject noun phrase, and so on. There are words that fail to exhibit the full range of properties. Groceries, in I bought some groceries, looks like the plural of a noun grocery – yet there is no such noun (*I bought a grocery), neither can groceries take numeral quantifiers (*five groceries). Syntactically, groceries is a somewhat marginal noun (though still a noun). However, there are words whose status is genuinely unclear. Consider saying, in without my saying a word. Being the complement of a preposition, my saying a word looks like a noun phrase, headed by saying, and saying looks like a noun, in that it takes possessive my. Other determiners, though, are not possible (without *the/*that/*a saying a word). Moreover, saying is followed by what looks like a direct object (a word), and the ability to take a direct object is a distinctly verb-like property, not at all a property of nouns.

Both semantic and formal criteria, then, fail to deliver clear-cut lexical categories. Nevertheless, there is an important sense in which the semantic prototypes have priority. Any language has to provide its speakers with the means to refer to 'things' and 'events,' 'properties' and 'relations,' and the semantic prototypes of the lexical categories, in English and other languages, are understood in such terms. Indeed, without the semantic prototypes, there would be no basis for recognizing the categories 'noun' and 'verb' across the different languages of the world.

Psychiatric Assessment: Negative Symptoms

Hans-Jurgen Möller, Ludwig Maximilian University, Munich, Germany

Abstract

Clinicians differentiate between positive and negative symptoms. Positive symptoms (e.g., of schizophrenia) are feelings or behaviors seen in the mentally ill that are not usually present in healthy humans, for example delusions and hallucinations. Negative symptoms, likewise, are feelings or behaviors normally present in healthy people that are lacking in the unwell, such as flattening of affect, poverty of speech and social withdrawal. They occur in different mental disorders, especially in schizophrenia. In schizophrenia, they are the phenomenological counterpart of positive symptoms. Both classes of symptoms might be related to different underlying pathophysiologies. The standardized assessment of negative symptoms is not without problems. In the last decade, efforts have been made to improve the assessment of instruments to overcome these diagnostic limitations.

Negative symptoms broadly comprise blunted affect, apathy, attentional impairment, poverty of thought or speech, incoherence, loosening of association, and social withdrawal. The origins of the positive/negative terminology are usually attributed to Jackson, a British neurologist of the last century, who drew the distinction in order to delineate primary from secondary neurological phenomena.

Today, the concept of negative symptoms is especially associated with schizophrenia/schizophrenic disorders; negative symptoms were described as an important part of the clinical symptomatology of schizophrenia already at the beginning of this century by Bleuler and Kraepelin, when the concept of schizophrenic disorders was developed. However, negative symptoms not only are specific for schizophrenia/schizophrenic disorders, but also found, for example, in affective disorders. In the last decades, efforts have been made to improve the standardized assessment of negative symptoms. Especially the introduction of several novel/atypical antipsychotics, which were thought in the last decade of the twentieth century to have better efficacy in negative symptoms compared to classical antipsychotics, increased the interest in clinical research on negative symptoms. The positive/negative distinction may represent different manifestations of a common underlying process. However, it may also suggest the existence of different pathophysiologies in schizophrenia/schizophrenic disorders.

Definition of Negative Symptoms

Negative symptoms in schizophrenia comprise broadly blunted affect, apathy, attentional impairment, poverty of thought or speech, incoherence, loosening of association, thought blocking, and social withdrawal. However, there is no unanimous agreement on the concept of negative symptoms in schizophrenia: some authors adhere to a broad interpretation (Meltzer and Zureick, 1989; Rösler and Hengesch, 1990), while others prefer a narrow approach (Crow, 1985; Strauss et al., 1974; Wing, 1989). The controversy centers on incoherence, loosening of association, and thought-blocking since these were also attributed to positive symptoms. This disparity in the selection of items also manifests itself in the outcome of patient testing with different rating scales. Different authors use different concepts and definitions for the type and number of symptoms implicated.

These problems of definition can also be identified in the rating scales used for measuring negative symptoms.

History of the Term 'Negative Symptoms'

The origins of the positive/negative distinction are usually attributed to Jackson (1887), the British neurologist who drew the distinction in order to delineate primary from secondary neurological phenomena. Accordingly, positive symptoms are defined as the presence of a behavioral function that is otherwise not normally present in an individual. Negative symptoms are defined as the absence of a behavioral function that is usually present in the normal individual. Negative symptoms all appear to be characterized by the loss of an important cognitive or behavioral function, while positive symptoms represent an exaggeration or distortion of a normal function.

Standardized Assessment and Dimensional Differentiation of Negative Symptoms

To improve the reliability of diagnostic assessment of negative symptoms, several scales have been developed, mostly in the last two decades (SANS, Andreasen, 1981; negative subscore of the PANSS, Kay et al., 1987; NSA, Alphs et al., 1989; CAINS, Horan et al., 2011). Standardization of the assessment of negative symptoms through rating scales had a positive effect on inter-rater reliability. For example, the interclass correlations for the Scale for the Assessment of Negative Symptoms (SANS) and the Scale for the Assessment of Positive Symptoms (SAPS) with complex global ratings range between 0.70 and 0.88. Principally, the negative symptoms ratings have a somewhat lower inter-rater reliability than the inter-rater reliability of positive symptoms. The most recently developed scales claimed an increased inter-rater reliability, even in an international perspective, and improved validity.

Rating scales applied in the past decades included, among others, the anergia score of the Brief Psychiatric Rating Scale

 http://dx.doi.org/10.1016/B978-0-08-097086-8.27041-4

(BPRS), the Manchester Scale and Crow's modification of this scale, the negative score of the Positive and Negative Scale (PANSS), the SANS, and Abrams and Taylor's Rating Scale for Emotional Blunting. Nowadays, the SANS and the PANSS are the most frequently used rating scales. It is not predictable whether these standard scales will be replaced more and more by the recently developed scales.

In nearly all studies in which a broad spectrum of negative symptoms was investigated by a factor analytical approach, two or three or sometimes even more dimensions of negative symptoms were found. This emphasizes the inadequacy of a unidimensional concept of negative symptoms in the complex phenomenology of this domain (Meltzer and Zureick, 1989; Horan et al., 2011).

Symptomatic Overlap with Depression and Parkinsonism

The differentiation between depression and negative symptoms is difficult on the basis of both clinical phenomenology and rating scales, and therapeutic effects on depressive symptoms might be misinterpreted as successful treatment of negative symptoms and vice versa. Gaebel (1989) reported a correlation of $r = 0.34 - 0.57$ at different measurement points for the BPRS subscores depression and anergia. In a follow-up study on schizophrenic patients, the correlation between the scores for depression and retardation/apathy in the Inpatient Multidimensional Psychiatric Scale (IMPS) amounted to $r = 0.35$ (Möller and von Zerssen, 1986). To overcome this problem, the Calgary Depression Scale was developed, which diminishes the overlap between negative symptoms and depressive symptoms.

Another problem in the interpretation of rating scale data from studies in this field is that the negative symptoms score correlates positively with scales measuring the neuroleptic-induced Parkinson syndrome. Furthermore, there is a correlation between negative symptoms and hyperkinetic neurological symptoms such as akathisia and dyskinesia. One could therefore conclude that drugs without extrapyramidal side effects, in general, may appear to be more advantageous in treating negative symptoms.

Negative Symptoms in Schizophrenia

Both Kraepelin and Bleuler described a core of schizophrenic symptoms corresponding to the modern concept of negative symptoms (**Table 1**). Later, this position was gradually displaced by an emphasis on productive features as being pathognomonic of schizophrenia, in fact, as being a prerequisite for its diagnosis. This is exemplified in the diagnostic criteria for schizophrenia put forward by Schneider 1959, in the research diagnostic criteria (Feighner et al., 1972), and in the *Diagnostic and Statistical Manual DSM-III*, *DSM-III-R*, and *DSM-IV* criteria (Spitzer et al., 1978).

The need to incorporate both negative and positive features into a model of schizophrenia was brought out by the factor analytic studies of the 1960s and in particular by the research of Strauss et al. (1974), who adapted Jackson's (1887) terminology for classifying different profiles in schizophrenia.

Table 1 Relationship between the concepts of basic and negative symptoms

Kraepelin (1904)	*Bleuler (1911)*	*Wing and Brown (1970)*	*Strauss et al. (1974)*
Cognitive decline ('stultification,' 'dementia')	Association disorder	Schizophrenic thought disorders, slowness of thought, and poverty of speech	Certain kinds of formal thought disorders, such as blocking
Flatness of affect	Affective disorder		
	Autism	Flatness of affect	Blunting of affect
Loss of intentional power	Ambivalence abulia, lack of initiative	Social withdrawal, low motivation	
Loss of energy	Lack of interest	Lack of initiative, underactivity	Apathy

Reproduced from Klosterkötter, J., 1990. Minussymptomatik and kognitive Basissymptome [Minus symptoms and basic cognitive symptoms]. In: Möller, H.J., Pelzer, E. (Eds.), Neuere Ansätze zur Diagnostik und Therapie schizophrener Minussymptomatik [Newer Approaches to the Diagnosis and Treatment of Schizophrenic Minus Symptoms]. Springer, New York, Berlin, Heidelberg, pp. 15–24.

Whereas Crow's (1980b) model viewed the positive and negative symptoms as annulated facets of schizophrenia that may reflect separate pathological processes, Andreasen (1982) proposed instead a typological model, which described positive and negative symptoms as opposing features that characterize different subtypes.

Which symptoms of schizophrenia are considered positive or negative varies across different authors. Nearly all authors include flat affect and poverty of speech among the negative symptoms and hallucinations and delusions among the positive symptoms. Most regard anhedonia, apathy, avolition, and abolia as negative symptoms. Thought disorder, bizarre behavior, and inappropriate affect, however, are variably classified as positive or negative.

Negative Symptoms in Other Psychiatric/Mental Disorders

Anergia, anhedonia, poverty of speech, and affective flattening, which occur as part of the negative symptoms in schizophrenia, are also observed in patients severely ill with depressive disorder. Although negative symptoms of schizophrenia may be different from depressive symptoms in depression, they do overlap, thus making negative symptom complexes and psychomotor retardation, lack of energy, anhedonia, and other symptoms of depression significantly associated. On the other hand, it was observed that a distinct hypokinetic syndrome involving anhedonia, depressed mood, and cognitive impairment existed not only in negative schizophrenia and retarded depression but also in Parkinson's disease, suggesting that reduced dopamine turnover might play a role in the pathophysiology of each.

Primary and Secondary Negative Symptoms

For theoretical and practical reasons, it is very important to differentiate between different types of negative symptoms (Möller, 2007). Especially the differentiation between primary and secondary negative symptoms, as proposed by Carpenter et al. (1985), seems of great relevance. While primary negative symptoms are part of a morbogenic deficit state, secondary negative symptoms are the consequence of

1. positive symptoms (e.g., social withdrawal because of paranoid ideas);
2. extrapyramidal effects (e.g., motor retardation as an indicator of neuroleptogenic akinesia);
3. depressive symptoms (e.g., postpsychotic or pharmacogenic depression); or
4. social understimulation (e.g., hospitalization).

According to this distinction, the treatment of negative symptoms has to be differentiated concerning the different causes.

Angst et al. (1989) underlined the necessity of discriminating negative symptoms according to different stages in the course of schizophrenia, i.e., the prepsychotic period, the productive psychotic period (characterized by a mixture of positive and negative symptoms, whereby negative symptoms may be hidden at this stage), and the postpsychotic period (characterized by a residuum with or without positive symptoms, postpsychotic endogenous, or reactive depression, postremissive exhaustion).

Crow (1980a) postulated the stability of a specific subtype of schizophrenia with positive symptoms (type I) and a subtype with negative symptoms (type II), explaining this by different biological causes. Most other authors stressed the point that negative and positive symptoms can be combined cross-sectionally or longitudinally and cannot be taken as indicators for a specific biological or phenomenological subtype of schizophrenia.

Relationship Between Positive and Negative Symptoms in Schizophrenia

The positive/negative distinction may represent different manifestations of a common underlying process. It may also suggest the existence of different pathophysiologies in schizophrenia. Hints about the inter-relationships of these processes may be gleaned from the intercorrelations among their final common expressions as symptomatic phenomenology. An initial effort by Andreasen (1982) showed that the positive and negative symptoms clusters were significantly correlated within clusters and inversely correlated between clusters, suggesting a bipolar construct with positive and negative symptoms at the opposite ends of a continuum. This was replicated by another group. However, later investigations showed little or no relationship between positive and negative symptoms, strongly suggesting that they are independent processes within schizophrenia.

Since both positive and negative symptoms are frequent in schizophrenia, they are likely not to be completely independent (Möller et al., 2010). However, some findings have been controversial. For example, Rosen et al. (1984) failed to find a positive/negative symptom correlation.

Course of Negative Symptoms in Schizophrenia

Data on the course of negative symptoms are mostly not from spontaneous/natural course, but from therapeutic intervention studies, among others randomized control group studies, observational studies with defined treatments or follow-up studies with insufficient information about treatments. In acute first episode or remanifestation cases, negative symptoms are tightly linked to the presence of other manifestations of psychoses, especially to positive symptoms (Möller and von Zerssen, 1986). In several studies on the effect of neuroleptics, also called *antipsychotics*, in acute schizophrenic episode, antipsychotics reduced the negative symptoms, together with the positive symptoms, significantly (Möller, 2003).

Overall, negative symptoms appear to be more stable in subacute/subchronic patient samples. Pogue-Geile and Harrow (1985) recorded high and stable levels of anhedonia 1 and 3 years after episodes of schizophrenia. Biehl et al. (1986) found that negative symptoms had significant retest stability between years 2 and 5 in a sample from the International Pilot Study of Schizophrenia. In a 5-year follow-up study of schizophrenia carried out in Munich (Möller and von Zerssen, 1986), a decrease was observed in the mean score of positive symptoms and also in the syndrome retardation as an indicator of negative symptoms. The correlation for the retardation score between discharge and follow-up was 0.36. In a more recent 15-year follow-up study on first hospitalized patients with schizophrenia, a decrease of negative symptoms was found between admission and discharge and an increase between discharge and follow-up. At discharge the score of negative symptoms was higher than the score of positive symptoms, indicating that under long-term conditions they are more relevant than positive symptoms (Möller et al., 2010).

Many authors came to the conclusion that, in contrast to the views of Crow (1980b), the negative subtype and the positive subtype of schizophrenia are not stable conditions during the short- or long-term course of the disease. Most authors stressed the point that negative and positive symptoms can be combined cross-sectionally or longitudinally and cannot be taken as indicators of a specific biological or phenomenological subtype. To make the picture even more complicated, there is also a relatively close association with cognitive disturbances which together with the negative symptoms are interpreted as core symptoms of schizophrenia. Very important is that negative symptoms are closely associated with poor social functioning and therefore better treatments are urgently needed.

Biological Correlates of Negative Symptoms in Schizophrenia

The most prominent biochemical finding in schizophrenic patients with negative symptoms appears to be the reduction in central dopaminergic, serotonergic, and noradrenergic activities, and, if at all, a general common pattern can be described.

This decrease in amine activity tends to be associated with structural brain abnormalities, i.e., cortical atrophy or enlarged ventricles. There are indications that neuroleptics/antipsychotics reduce at least those negative symptoms of schizophrenia that are secondary to positive symptoms when the positive symptoms are effectively treated. However, negative symptoms of schizophrenia that occur independently of positive symptoms may also be reduced, especially through treatment with atypical antipsychotics, also called second generation antipsychotics, or by comedication with antidepressants or other compounds, e.g., glutamatergic compounds (Möller, 2003, 2004). The efficacy of neuroleptic treatment of negative symptoms seems to be related to their pharmacological profile, i.e., their interference with dopaminergic, noradrenergic, and serotonergic receptor systems. As to atypical antipsychotics, among others, the 5-HT_{2A} blockade was hypothesized as being a relevant mechanism for the efficacy of atypical antipsychotics in treating negative symptoms. More recently, a glutamatergic hypothesis came into the focus of neurobiological and psychopharmacological research.

As mentioned above, there is a considerable overlap in the symptomatology of psychiatric disorders with respect to negative symptoms. Also, different types of negative symptoms in schizophrenia have to be considered. In addition, the lack of homogeneity in the definition and assessment of negative symptoms in schizophrenia can be a problem. All these difficulties have consequences for research and explain some of the inconsistencies in biochemical and pharmacological schizophrenia research. The results of biochemical investigations as well as of positron emission tomography and magnetic resonance imaging studies on negative symptoms warrant further research efforts in this field to find, among others, a more rational neuroleptic drug treatment in negative symptoms of schizophrenia.

Treatment of Negative Symptoms in Schizophrenia

There has been a strong debate in the literature on whether neuroleptics can really reduce negative symptoms, and especially whether they can reduce primary negative symptoms and not just secondary negative symptoms. Some earlier reviews found evidence that some antipsychotics, especially some atypical antipsychotics, can reduce negative symptoms. However, since most of the trials were carried out in patients with negative and positive symptoms during acute exacerbations of schizophrenic psychoses, the question arises whether only those negative symptoms were reduced that were secondary to positive symptoms. In addition, the overlap between negative symptoms of schizophrenia and extrapyramidal side effects and depression has to be taken into account. As an alternative hypothesis to the direct effect of a drug on negative symptoms, the possibility that a drug reduces depression, akinesia, sedation, etc., and in this way also reduces negative symptoms, must be considered seriously.

Clearer results of drug treatment of negative symptoms may be obtained if more sophisticated designs are used for psychopharmacological trials on negative symptoms.

A European collaboration group, therefore, made methodological suggestions as early as the 1980s (Möller et al., 1994) focusing on patients with predominantly negative symptoms (Table 2), which were later adopted by the European drug authority, EMEA.

One possibility of differentiating between direct and indirect drug effects on negative symptoms is to use special statistical procedures. Formerly, only two studies had used an elementary statistical approach to account for the possibility of indirect effects on negative symptoms. Meltzer (1985) used a covariance analysis and found that the neuroleptic effect on negative symptoms could not be explained via a neuroleptic effect on positive symptoms alone. van Kammen et al. (1987) used a regression analysis which showed that the neuroleptic effect on negative symptoms could be explained by the effect on positive symptoms. More complex statistical approaches were not used until the mid-1990s. Möller et al. (1995) applied a complex statistical model, a path analysis, to the data of the North American Risperidone Study (Marder and Meibach, 1994), including effects on positive, negative, and extrapyramidal symptoms, to determine whether the atypical antipsychotic risperidone had a more potent direct effect on negative symptoms than haloperidol. The aim was to determine whether the (direct) effect on negative symptoms remains after the effects which are possibly caused through the reduction of positive and extrapyramidal symptoms have been excluded. The estimate from the path model showed that even after statistical control for indirect effects on secondary negative symptoms, risperidone improved negative symptoms to a greater extent than haloperidol.

While after the advent of the atypical antipsychotics, also called second generation antipsychotics, there was some enthusiasm that these compounds might have a much better efficacy in negative symptoms than the first generation antipsychotics, in the following years this view was challenged by

Table 2 Suggestions of the working group on negative symptoms in schizophrenia

Aim: evaluating treatment effects on negative symptoms in schizophrenia
Patient selection
Positive symptoms not dominating the actual clinical picture, e.g., PANSS negative type
Duration of negative symptoms >6 months
Stable condition of the schizophrenic illness >6 months
Flat affect and poverty of speech as core symptom of negative symptoms
No/low depression score
Design: double-blind comparison to placebo or active drug
Efficacy parameters: BPRS or SANS or PANSS
Other scales: depression scales, EPS scales
Statistical analyses
End-point comparison
Interaction with productive symptoms, depression, EPS

BPRS, brief psychiatric rating scale; EPS, extrapyramidal symptoms; PANSS, positive and negative syndrome scale; SANS, scale for the assessment of negative symptoms.

Reproduced from Möller, H.J., van Praag, H.M., Aufdembrinke, B., Bailey, P., Barnes, T.R., Beck, J., Bentsen, H., Eich, F.X., Farrow, L., Fleischhacker, W.W., Gerlach, J., Grafford, K., Hentschel, B., Hertkorn, A., Heylen, S., Lecrubier, Y., Leonhard, J.P., McKenna, P., Maier, W., Pedersen, V., Rappard, A., Rein, W., Ryan, J., Sloth Nielsen, M., Stieglitz, R.D., Wegener, G., Wilson, J., 1994. Negative symptoms in schizophrenia: considerations for clinical trials. Psychopharmacology 115, 221–228.

a lot of studies which did not prove such a significant superiority (Tandon et al., 2008).

Currently there is some hope that new compounds based on other pharmacological mechanisms like glutamatergic effects might have stronger effect on negative symptoms. Beside psychopharmacological treatment, also psychotherapeutic approaches were developed, especially kinds of behavior therapy.

Abstract

The primary aim of a health care system is to improve the health of patients and families, and if available resources can be used more efficiently then greater health improvements can be achieved. Economic evaluations offer important insights. This article describes cost-effectiveness and related analyses, how they measure outcomes and costs, and how decision-makers can be supported in making trade-offs when better health outcomes can only be achieved at greater cost. Examples of mental health evaluations are used to illustrate these approaches.

Introduction

It sometimes feels as if it took a devastating global macroeconomic shock to wake some people up to the fact that resources are scarce. In fact, scarcity is the perennial state of the world: there are never enough resources to meet everyone's needs or to satisfy everyone's wants. Consequently, those individuals who control, manage, or allocate resources have to make tough choices about how to use them. This affects not only decision-makers at national strategic level, such as government ministers and chief executives of major corporations, but also almost every purchaser, provider, and professional within health, social care, housing, and other systems. It affects individuals, families, and communities too. Indeed, anyone juggling their own or their organization's budget – or managing nonmonetary resources such as their own or staff members' time, in-patient beds, therapy hours, or medicines – will be acutely aware that resources are almost never sufficient to respond positively to every demand or request for them.

If we assume that each of these decision-makers is reasonably rational, then they are likely to want to use their available resources to achieve the best outcomes. In the health field, those outcomes might be gauged in terms of how well needs are met, or symptoms alleviated, or pain reduced, or normal functioning restored, or quality of life improved. This is where economics can be helpful: a core aim of economic analysis is to help decision-makers to achieve the goal of using available resources so as to achieve the best possible outcomes. In this article I will look at economic evaluation – particularly cost-effectiveness analysis and some of its variants – and how it can support decision making. I will describe what cost-effectiveness analysis aims to do, and what information it needs, offering some illustrations from the psychiatric field.

Decisions-makers face tough choices between competing uses of scarce resources. How does a hospital decide how many resources should be allocated to each medical specialty, or what the balance should be between in-patient and out-patient services? How does a clinician or clinical team decide which individuals should be treated and in what priority order? When offering treatment, which medication or psychological therapy or other approach should be chosen for which patients? Looking more broadly, what proportion of available resources should be spent addressing today's needs and what proportion should be invested in strategies that could prevent the emergence of new needs? Broader still, how does a national or regional government decide how much to allocate to health rather than (say) education, housing, or the armed forces? None of these questions is solely or even primarily an economic issue, and none of them will be answered satisfactorily only with economic evidence. But each and every one of these questions has an economics element, because whatever decision is taken will undoubtedly have economic implications. Evidence from an economic evaluation can therefore help the decision-maker with those difficult choices. At the same time, these decision-makers will need and want to weigh up other considerations such as fairness, equity of access, dignity, environmental sustainability, and so on. These are all valid and important aims, but I will not be covering them here.

Economic Evaluation

Among the key questions that need to be addressed when considering whether to license, recommend, prescribe, purchase, or use a particular intervention, two are particularly pertinent here. (I will use the term 'intervention' generically in this article, covering services, treatments, preventive strategies, or wider policy initiatives.) The first question is 'Does it work?': is the intervention effective in reducing or removing psychiatric symptoms, or improving health-related quality of life, or achieving other outcomes? If the answer to this first question is likely to be yes – that is, if the intervention appears to be effective – then the second question to be addressed must be 'Is it worth it?': is the cost of the intervention worth incurring in order to achieve that level of effectiveness? This second question is what an economic evaluation such as a cost-effectiveness analysis tries to answer. However, neither of these two questions can be answered adequately without reference to some comparator, even if that comparator is 'doing nothing' (placebo).

This then suggests that there are basically five steps for an economic evaluation of the cost-effectiveness kind:

1. the question that needs to be answered by the evaluation needs to be made clear;
2. two or more interventions are then compared;

3. the outcomes of each intervention are assessed;
4. the associated costs of each intervention are measured; and
5. the trade-offs between better outcomes and higher costs are then considered.

Economic evaluations can be employed to answer quite broad and also relatively narrow questions, and it is important to be clear what the purpose of the study is; I discuss this in Section The Evaluative Question to Be Answered. The best way to make a comparison might be to carry out a randomized controlled trial, although other approaches might be suitable in some circumstances. I will not rehearse the arguments for and against randomized trials here, but I will later describe how simulation modeling can supplement or extend trial data (Section Modeling). The outcomes to be assessed will depend crucially on what question the evaluation is seeking to address; I briefly discuss the options in Section Effectiveness and later introduce two types of outcome measure that health economists have often employed: utility (Section Utility Measurement) and monetary benefits (Section Monetary Benefits). Cost measurement is discussed in Section Costs, not just in terms of health system resources used to deliver the interventions, but also the wider resource implications to health care and other systems and to patient and families. The final element of an economic evaluation – bringing the outcome and cost findings together – is considered in Section Making Trade-Offs. Some of the challenges and issues raised by economic evaluation are discussed in Section Some Issues and Challenges, before a brief conclusion (Section Conclusions).

The Evaluative Question to Be Answered

There are a few different 'types' or approaches to economic evaluation, as described below, but they share some common features. In particular, they share a common approach to the conceptualization, definition, and measurement of costs, as outlined in the next section. The main differences between the approaches are with respect to how they define and assess outcomes; these differences arise primarily because different approaches are needed to answer slightly different questions.

If the question addressed by an economic evaluation relates to patients with a particular clinical need (such as severe depression or Alzheimer's disease) and is concerned with the economic case for one therapy over another, then the outcomes that are most relevant are those specific to the diagnosis (such as alleviation of depressive symptoms or slowing down of cognitive decline) as well as some more general indicators (such as quality of life and personal functioning). In this case, health economists would carry out a form of evaluation called cost-effectiveness analysis. It is the most commonly conducted type of economic evaluation in the health field, with hundreds of new studies published each year, quite a few of them in the area of psychiatry. In this evaluative approach, outcomes are measured in exactly the same way as the clinical researcher would want to measure them, and costs are measured with greater or lesser breadth, depending on the context (see Section Costs). A cost-effectiveness analysis tells decision-makers what course of action (e.g., what treatment) most efficiently addresses a specific set of clinical needs. Some examples are given below.

Some decision-makers face broader questions. For example, they may need to decide whether to treat more people with depression rather than spending their available funds elsewhere in the health system, say on treating coronary heart disease. If that is the case, they not only need to know the costs of the different options, but also some common measure of outcome that would allow them to compare the impact of depression treatment with the impact of coronary heart disease treatment. Because diagnosis-specific symptoms are quite different between depression and coronary heart disease, a generic outcome measure is needed that has relevance in both clinical areas. Economists have developed the 'utility' measure, often operationalized in terms of quality-adjusted life years (QALYs), which I will come back to in Section Utility Measurement. Another generic measure is the disability-adjusted life year, more commonly used in evaluations in low-income countries, but also widely employed as a generic way to compare levels of 'disability burden' across disease areas and countries (e.g., Murray et al., 2012). Using a generic outcome measure like a QALY, it is possible to conduct a cost-utility analysis. This form of evaluation tells the (strategic) decision-maker where they will get the biggest impact – across a range of clinical areas – in terms of health-related quality of life relative to the resources expended.

The evaluation could be broader still, especially if the decision-maker needs to choose how to allocate resources between (say) expenditure on health care, broadly defined, and expenditure in another arena, such as education or social care. Once again, the economic evaluation would need to compare costs between the various alternatives, which is usually straightforward, but now outcomes would need to be measured to allow sensible comparison. One way to do this is to value those outcomes in monetary terms; this is what health economists call a cost-benefit analysis (see Section Monetary Benefits).

We can therefore see how the policy or practice question that the evaluation needs to address will influence the type of economic evaluation that should be carried out. However, as shown in some of the illustrative studies set out later, a single study can usually support more than one evaluative approach if the right measures are employed.

Costs

Some costs are directly associated with the treatment of a disorder, such as the money spent on medications and psychiatrists' salaries. Other costs are indirect, such as lost productivity because of ill-health, which can be very high in the mental health area (Organization for Economic Cooperation and Development, 2012), or the family cost of unpaid care and support, which can be even higher, for example in the case of dementia (Alzheimer's Disease International, 2010). Productivity losses arise because of absenteeism, reduced performance while at work ('presenteeism'), early retirement, reduced opportunities for career development, days 'out of role' for people not in paid work, and reduced lifetime productivity due to premature mortality. Costs for unpaid carers stem from similar productivity losses, as well as out-of-pocket expenses (payments for treatment or to transport the

person with mental health needs no services) and psychological strain.

An economic evaluation would therefore need data on the services individuals use and how frequently they are used and the unit (average) costs of each of them (Knapp and Beecham, 1990). Other data would be needed on the impact of poor mental health (and of effective treatment) on productivity, such as absenteeism or unavailability for work, and on the associated costs, usually approximated by a typical or average national wage rate (under the assumption that wage equals marginal productivity). If an individual receives support from a family member or other unpaid carer, then the amount of such support provided (e.g., the number of hours in a week) would need to be estimated and again a cost attached to those hours. Some researchers would value these hours of unpaid care at a typical wage rate, and some have used a replacement cost approach (taking a value equal to the cost of employing a homecare worker, for example).

Effectiveness

Arguably the most intuitive type of economic evaluation to a psychiatrist or mental health decision-maker is cost-effectiveness analysis (CEA), which measures costs as set out above and outcomes along dimensions that would be recognized by clinicians and other service professionals, such as changes in symptoms, behavior, functioning, and health-related quality of life. A CEA can then help decision-makers choose between interventions aimed at specific health needs, such as two different treatments for depression. For example, change in depressive symptoms could be measured using the Hamilton rating scale (Hamilton, 1960), and then the evaluation would compute the difference in costs between two interventions over a specified period of time (say 6 months) and the difference in the change in Hamilton score over that same period. If one intervention achieves a greater change in Hamilton score than the other, and is also the less costly of the two, then it would be straightforward to see that it is more cost-effective – it improves outcomes and saves money.

An example can be given from a study comparing two treatments for people with severe depressive episodes (unipolar or bipolar): electroconvulsive therapy (ECT) with repetitive transcranial magnetic stimulation (rTMS). Outcomes were assessed at the end of treatment, and then 3 and 6 months later, and costs calculated during the treatment period and over the 6-month follow-up. On the primary outcome – the Hamilton rating scale – ECT was significantly more effective at the end of the treatment period, but by the 6-month follow-up point there was no difference between the treatment groups. On the secondary outcome measures – mood self-ratings on the Beck Depression Inventory (BDI; Beck et al., 1996) and the Brief Psychiatric Rating Scale (Overall and Gorham, 1962) – patients randomized to ECT were doing better at the 6-month follow-up point (Eranti et al., 2007). Costs were significantly lower for the ECT group than the rTMS group over the 6-month period, and rTMS was clearly more cost-effective than ECT (Knapp et al., 2008).

A cost-effectiveness analysis does not have to be confined to a single outcome measure (in which case it is sometimes called a cost-consequences analysis). Now the evaluation looks at the cost differences and a range of effectiveness differences – one for each relevant outcome dimension. The economic evaluation of ECT and rTMS not only had Hamilton as the primary outcome but also calculated QALY gains over the evaluation period. These were based on the SF-6D measure (Brazier et al., 2002), with societal weights attached. The economic evaluation could therefore compute incremental cost-effectiveness ratios for each outcome measures in turn. There was no difference in QALY gain between the interventions.

This cost-consequences approach has the advantage of breadth, but poses a challenge if one intervention is found to be comparatively better on one outcome measure, but comparatively worse on another. The preferred option in this case is not clear and decision-makers must weigh up the strength of evidence, perhaps on the basis of value judgments about the relative importance of the respective outcome dimensions.

Making Trade-Offs

An intriguing and difficult challenge in an economic evaluation – and obviously in the very real world of decision making – is the scenario mentioned just now: when one intervention is more effective than another but also has higher costs. Which of the two interventions then represents the best use of resources? The answer hinges on the extent to which the decision-maker is prepared to trade-off better outcomes for lower costs. In other words, what is the decision-maker's willingness to pay for the better outcomes? Not surprisingly, there is no single or simple answer: it is a matter of value judgment.

The usual way to present evidence from an economic evaluation to illustrate this trade-off is to calculate the incremental cost-effectiveness ratio. This ratio divides the extra cost associated with a new intervention by its additional effect. For example, in a study of computerized cognitive behavioral therapy (CCBT) compared to treatment as usual for people with depression or anxiety, it was found that CCBT was better in terms of alleviating symptoms and improving work and social functioning over an 8-month follow-up period (Proudfoot et al., 2004), but it was also more expensive to the health service (McCrone et al., 2004). The cost of achieving an incremental improvement in symptoms as measured by the BDI – i.e., the difference in cost between CCBT and usual care, divided by the difference in BDI score at the follow-up point – was calculated to be £21, equivalent to a cost of £2.50 per depression-free day over the follow-up period. The decision-maker must decide if that additional cost is worth paying.

Health economists often use cost-effectiveness acceptability curves (CEACs) to show the trade-off that a decision-maker will need to make in order to decide whether higher costs are justified by better outcomes (Petrou and Gray, 2011). In the case of the CCBT evaluation, the plotted CEACs showed that, even if the value placed by the decision-maker on a unit reduction in the BDI was as low as £40, there was still an 81% probability that CCBT would be cost-effective. Similarly, assigning a societal value of just £5 to each additional depression-free day would result in an 80% probability that CCBT would be cost-effective (McCrone et al., 2004).

Utility Measurement

Some decisions about resource allocations require comparisons to be made that are beyond a specific diagnostic context, such as when setting departmental budgets within a hospital or taking strategic decisions about which health needs to prioritize. As mentioned earlier, economists have developed a single, over-arching measure called utility, usually operationalized as a preference-weighted, health-related quality-of-life measure, with the QALY being the best-known and most widely used (Petrou and Gray, 2011). Values are elicited from the general public on the quality of life associated with different states of health (through a series of robust field studies), with a value of 1 being assigned to a state of perfect health and a value of 0 assigned to death. The extra years of life that flow from an intervention can then be weighted by the quality of each of those years.

The study of CCBT introduced earlier included an assessment of QALYs. These were approximated from the BDI: the cost per QALY was £2190, the interpretation of which will be discussed later. It is more common to use a specific QALY-generating tool; the EuroQol (EQ-5D) is one such most widely used measure (EuroQol Group, 1990). An example of an evaluation that took this approach looked at a manual-based coping strategy intervention for family carers of people with dementia, comparing the new program to support as usual in a randomized controlled trial (Knapp et al., 2013b). Carers in the intervention group were found to have better outcomes as measured in terms of both affective symptoms (Livingston et al., 2013) and QALY gains. Costs were actually slightly higher for the carers who received the coping strategy intervention, compared to those who were supported as usual, with the cost-effectiveness ratio being £6000 per QALY gained. How is this ratio to be interpreted?

In England and Wales, the National Institute for Health and Care Excellence (NICE) employs a framework to help the groups developing its clinical, public health, and social care guidelines to decide whether better outcomes are 'worth' the higher costs sometimes necessary to achieve them. Their approach uses the generic QALY measure of health outcome and suggests a threshold value for cost-effectiveness: a medication or other intervention that costs more than £20 000 per QALY would generally not be considered 'worth' it since – NICE would argue – the resources (represented by the cost) could probably be better spent somewhere else in the health system. This threshold is only there to provide guidance – it is certainly not a rigid rule – but has the signal virtue of reminding everyone – doctors and nurses, patients and carers, taxpayers, and voters – that resources are not limitless, and that difficult choices have to be made about how to deploy them (Appleby et al., 2007; Cerri et al., 2014). Some other countries have now established similar processes to guide allocation decisions (McDaid and Cookson, 2003).

Almost every health economic evaluation would use a QALY measure nowadays, but always alongside symptom or similar 'clinical' measures of outcome. Although it is the most widely used QALY-generating tool, the EQ-5D does not always perform as sensitively as needed in research on treatments for some severe mental health problems or for the youngest or oldest patients (Brazier, 2010). This difficulty has encouraged the development of disease-specific tools to measure QALYs, such as the DEMQOL-U for studies of people with dementia (Mulhern et al., 2012).

Monetary Benefits

Cost-benefit analysis is a useful form of economic evaluation. Because costs and outcomes (benefits) are now measured in the same monetary units it is possible to see whether the benefits exceed costs, that is, whether the evaluation provides support for the intervention to go ahead. With two or more interventions to be compared, the one with the greatest net benefit (the difference between benefits and costs) would be seen as the most attractive from the efficiency standpoint. Cost-benefit analyses are also useful when decision-makers have to allocate resources across different sectors (e.g., health care, housing, education, and so on). But they are also intrinsically difficult to do, because it is generally not easy to convert a clinical outcome measure such as an improvement in symptoms or quality of life into a monetary value.

One of the few cost-benefit analyses carried out in the mental health area evaluated Individual Placement and Support (IPS) for people with severe mental health problems who are unemployed but would like to work, compared to standard vocational rehabilitation. IPS has a lot of promise as an approach to establish people in paid employment (Bond et al., 2012), but almost all studies have been carried out in a single setting. A randomized controlled trial was conducted to examine the economic case for IPS within and between six European countries (Burns et al., 2007). Two primary outcomes were chosen: additional days worked in competitive settings and additional percentage of individuals who worked at least one day. The former could be converted to a monetary measure by attaching a value equal to average gross wage (assumed to be equal to the value of productivity added to the economy). The study found a large difference in net benefit in favor of IPS, representing a more efficient use of resources than standard vocational rehabilitation (Knapp et al., 2013a).

Modeling

A randomized controlled design is undoubtedly the most robust approach to adopt in order to answer a range of questions, such as when deciding which medication is better for the treatment of a particular illness, and the examples above offer illustrations of how such a design can easily accommodate an economic evaluation. But a randomized design might not always be feasible in evaluating whether, say, some preventive strategies are effective or cost-effective. It might also be infeasible, and possibly unethical, to ask people to remain in randomly allocated groups for many years while the research team gathered data to assess long-term consequences of different interventions. Moreover, decision-makers today often want evidence somewhat faster than would normally be possible with a study that is collecting new information (primary data).

An approach that can sometimes be used is some form of mathematical modeling such as a simple decision tree or

a Markov approach, populated with data from previous trials, observational studies, or routine management information systems (secondary data). Models are representations of what might happen in reality, for example, tracing pathways through care for individuals with particular characteristics or needs; estimating the associated outcomes and costs; and then comparing them in order to gauge whether one is more effective, cheaper, or more cost-effective than the other (Briggs et al., 2006). Models are more generalizable and flexible than studies that collect primary data, and they can also generate findings much earlier. But they are clearly simplifications of reality and can only be as good as the data available to populate them, so that their limitations do need to be borne in mind.

Some examples can be offered. There has been extensive research on parenting programs: Bonin et al. (2011) modeled the economic pay-offs from parenting programs where there is a child in the family with a conduct disorder. Based on data gathered by others in around 20 randomized control trials, they examined the economic case for parenting programs over 25 years by tracing through the possible consequences for service use (health, social care, special education), contacts with the criminal justice system (particularly in adolescence and early adulthood), and patterns of employment. The cost of a parenting program averaged around £1200 per family in 2008–09 prices, but the economic return over a 25-year period was calculated to be between 2.8 and 6.1 times greater than this intervention cost.

A similar modeling approach was employed in investigating the economic case for 15 mental health promotion and mental illness prevention initiatives (Knapp et al., 2011). For each intervention, there was already well-established evidence of effectiveness. The aim was to examine whether there were economic pay-offs from these interventions in terms of direct (immediate or longer-term) cash savings to the public sector, to employers, or to the wider society (e.g., through crimes averted). Investigating the wider impacts was important, given the extensive impact of many mental health problems. The research gave national and local decision-makers information on whether interventions they were keen to promote on the grounds of health improvement and quality-of-life gains were also at least affordable or perhaps even generated significant economic gains.

Some Issues and Challenges

Economic evaluations can be carried out from a range of perspectives: looking only at the economic impacts on the health system perhaps, or on the government sector, or on the whole of society. Different perspectives for a study are driven by a need to answer slightly different policy or practice questions. The perspective adopted will have implications for how broadly costs are measured, and it might also have implications for whether or not the intervention under study is found to be cost-effective.

Some interventions might lead to (relative) cost savings, which could be attractive to purchasers or policy-makers. However, sometimes those savings do not accrue immediately or they might be achieved in budgets other than the one from which the intervention was funded. Some savings might not be easily 'cashable,' such as when an intervention reduces hospital admissions but does not (immediately or perhaps ever) close beds or save expenditure as a result. Another saving that is not 'cashable' is when the burden of unpaid care from families is reduced. It is generally harder to argue the economic case for an intervention when its main impacts are some years away rather than immediately when any savings or other economic benefits are enjoyed in other sectors and when impacts cannot readily be turned into 'real' savings.

A related challenge is when an intervention does not actually reduce expenditure (i.e., it is not cost-saving), but it still appears to be a good use of resources because the outcomes it generate are considered to be worth it. As noted earlier, if one intervention has better outcomes and also higher costs, then a trade-off has to be made. At a time when budgets are under considerable pressure, it can be hard to persuade decision-makers to spend more than they are currently, even if the clinical benefits experienced by patients are impressive. The purpose of a health system, of course, is to improve health rather than to reduce expenditure, so an intervention that can substantially improve health ought to be given proper consideration. The difficulty is that the decision-maker only has so many dollars or euros to spend.

Conclusions

Decision-makers within health systems across the world need to balance their budgets. They need to do so while pursuing their primary objective, which is to maximize the impact that services and treatments can have on the health and quality of life of patients and families. This is a tough task. Resources are scarce relative to the demands for them, and also scarce relative to the needs of the population. The upshot is that careful choices always have to be made about to utilize those resources. Economics evidence should not dominate decision making in health, social care, or other systems, but it does need to be stirred into the mix along with evidence on what needs are or are not being met, what other outcomes are achieved, and how well care and support arrangements match up to the preferences of patients and families.

Psychiatric Social Work in the United Kingdom

Colin Pritchard, Bournemouth University, Bournemouth, UK; and University of Southampton, Southampton, UK

Abstract

Mental health services still face the dilemma of 'care versus control,' reflecting societal anxiety about mental illness. Psychiatric Social Work in adult services work as Approved Social Workers predominantly concerned with formal admission. In the Child and Adolescent Mental Teams the role is more integrative. Recent research indicates the importance of the interactive bio-psycho-social model to address the increases in Attention Deficit Hyperactivity Disorder (ADHD) and Autism and recognizes the psychiatric–child protection interface to prevent extremes of abuse, assisting children of psychiatric parents to deal with the impact of mental illness – thus making children safer and contributing to the reduction of subsequent problems in their adulthood.

Introduction: Socio-Historical and Policy Perspectives

Psychiatrist social work is a specialism within the profession and has developed differently in diverse parts of the world, although there will be recognizable elements, particularly those concerned with the stigma usually associated with mental ill health, that cross borders. In this article, I consider the development of psychiatric social work primarily in the UK. As I have been a psychiatric social worker for most of my professional career, the history of this specialism in this country is intertwined with my own journey within it.

The social policy analyst Richard M. Titmuss (1965: p. 4) said, "Reality starts with history." Britain's provision for people with mental health problems emerged from medieval ideas and beliefs about 'possession.' This then assumed the need for a priestly intervention, until influenced by the 'Enlightenment.' This resulted in a slow movement toward an effort of 'caring' for the 'deranged,' albeit with strong control elements because of fears of "moon-struck madness, moping melancholia and demonic frenzy" (Milton, 1674: p. 485).

Psychiatric Social Work (PSW) in the United Kingdom over the past 50 years coincides with my career, because in 1957 I admitted my first compulsory admission under the 1890 Lunacy Act. This was to the local county mental hospital, which in the 1950s typically held almost 2000 patients, of whom less than 20% were 'Voluntary,' having been admitted under the 'modernizing' Mental Health Act 1930. Thus we struggled with the issue of care versus control. An example of this dilemma was seen in a high-profile tragedy where a European Senator killed his mother. Due to his status, the case was referred personally to the country's President, who decreed:

> if he was insane when he killed his mother and not pretending to be insane, you are not to be concerned about punishment because insanity is punishment enough … [however] … You tell me he was in the care of friends and guardians when the murder took place, therefore you should inquire whether there is a case that one or more were guilty of neglect and you should deal with them accordingly.

Students are surprised to learn that the 'President' in question was the second-century Roman Emperor Marcus Aurelius. Yet even this philosopher-Emperor asked if there was someone to blame – so, there is little that changes!

One early impetus for change followed the attack on the British King George III, by a delusional Mr McNaughton. However, the King showed some fellow sympathy and so McNaughton's Rules entered British case law. According to this law, mentally sick persons could not be held criminally guilty because of diminished responsibility, as their delusions make them incapable of understanding right from wrong (Brown, 2009). The 1890 Lunacy Act was concerned with safety; so the magistrates (and not 'doctors of the mad') admitted people to 'lunatic asylums.' Nothing in this Act mentioned treatment or discharge, so apart from response to families making an appeal, persons committed to the asylums were kept there and this law resulted in overemphasis on keeping people secure. What was intended to be a civilized refuge became repressive; and the asylums (created in 1813) became full and fuller.

A seminal attitudinal change took place following the First World War and the recognition of 'shell shock' (understood today as Post Traumatic Stress Disorder). Middle-class men of sensitivity, such as the war poets Wilfred Owen and Siegfried Sassoon, gave the wider public some idea of the pity and horrors of war.

Developments in the new medical specialty of psychiatry, and the realization that a mental breakdown need not be permanent, led to the 1930 Mental Treatment Act, which eliminated the term 'Lunatic Asylum' and facilitated short-term admission into 'Mental Hospitals', so that 'voluntary' admission' became an option for patients.

After the Second World War, under the reforming Labour Government, the Welfare State was introduced. In 1948 the Poor Law of 1601 was abolished. Social work developed along two lines: either as 'social' or as 'psychological' within the then various welfare services. For example, adult or elderly care (disability, homelessness) was more social and financial, whilst mental health and children's services were more psychological.

The modest changes implemented under the Mental Health Act 1930 however, did little to reduce the number of people incarcerated and this did not change until the seminal 1959 Mental Health Act (MHA), which placed the emphasis upon 'treatment'; and ensured that whenever possible, patients were admitted with minimal restrictions. The Psychiatric Social Workers' input was as Mental Welfare Officers (MWOs) who

increasingly were trained; and although they had a role in compulsory admissions, they were charged to seek minimum restriction for the individual and were responsible for the support of the patients in the community, seeking to make an alliance between patient and family. The success of the act was seen in the closure of the large psychiatric hospitals that had produced 'institutionalized' patients and staff.

The Mental Health Act of 1959 abolished the difference between general and psychiatric hospitals. All hospitals today have a psychiatric unit; and the only separate psychiatric service are the forensic units, concerned with people considered dangerous.

So, within 10 years, instead of most patients being 'certified,' nearly 90% had become 'voluntary,' Alongside a 'care-in-the-community' emphasis, the large mental hospitals were closed and patients went to psychiatric departments in general hospitals, reflecting Nye Bevan's great vision of integrating health and social care at the core of the National Health Service (NHS) Act of 1948. This is still ostensibly the aspiration for the NHS.

This period of progressive community care was linked to the new psychopharmacological medicines, giving confidence that people could be cared for and controlled in the community. However, there was the danger of the 'chemical cosh' and fears of 'soviet type psychiatry,' led by critics such as British psychiatrist RD Laing and Thomas Szasz from the USA, who challenged the authenticity of the concept of 'mental illness' (Pritchard, 2006).

The Development of Independent Social Work Departments

One problem that emerged following the establishment of the British Welfare State was that social work was spread across many different agencies, both public and voluntary. There was an overlap of services; whilst central government departments were responsible for national policy, the actual services were provided and delivered by the Local Authorities (LA). Thus the Children's Department, and Child, Adolescent, and Adult Mental Health, were the responsibility of the Departments of Health and Probation, the Home Office, the Educational Welfare Officer, the Department of Education and Housing, and Welfare Services under the Local Authority; it meant that the same family could be visited by six different Local Authority–based social workers and possibly other professionals from various voluntary agencies including the NSPCC, Moral Welfare, etc.

In part this was because of the impact of poverty, upon families, which even today has a deleterious impact on health and education (Pritchard and Williams, 2011; Pritchard et al., 2014), resulting in families occupying different life pathways. Thus, a mother (who might herself have been in child care) with poor parenting skills, giving rise to concerns about her children, may have had a partner, who could have been a previous or current offender in touch with the Police, Probation, and the Benefits Office. There could have been rent arrears and involvement with the Housing Department; the Education Welfare Officer (EWO) would have been concerned by the children's truancy; and the mother might have been referred to the mental health team for treatment of depression, by her GP (general practitioner). In this situation there was repetition and duplication of services; confusion and fragmentation occurred as different agencies focused only on their particular part of the problem. This was resolved following the *Seebohm Report* of 1968, leading to the creation of the integrated Local Authority Social Services Department, designed as a generic 'one-stop' agency, to bring all services together. However, Probation stayed separate under the Home Office.

Specialist social workers like PSWs (psychiatric social workers) quickly realized that Seebohm's message of a generic 'one-stop' inclusive agency was misunderstood. Thus specialist social workers, especially those offering mental health services, were discouraged by the local authorities, because there was concern that this new service would be independent of medical control (Pritchard, 2006).

These tensions coincided with the anti-psychiatry movement of the 1960s and 1970s, led by British and American critics epitomized by RD Laing and Thomas Szasz. Laing postulated that mental illness was a rational response to the modern world and parental oppression, which suppressed the person's 'real self.' He argued strongly against medicalization and overdependency on psychopharmacology, which led to neglect of the psychosocial dimensions.

Szasz was more philosophical, arguing that in order to differentiate between mental and physical illness and treat some behavioral/mental disorders "as if they were a physical illness," biological evidence should be required; he believed that "mental illness was a myth." Paradoxically, there is now a greater understanding of the constant bio-psycho-social interaction in the etiology of conditions recognized as 'psychiatric.' Descartes' division of mind and body is false; modern technology, (such as the brain scan) shows that there is a constant feedback loop and interactions between biological, psychological, and social stimuli (Baron-Cohen, 2011; Buckingham and Daniolos, 2013; Koss et al., 2014; Palmer et al., in press).

One dilemma in Western psychiatry is that some wish to be accepted by mainstream medicine while others are more psychosocially orientated. However, pressure upon resources makes it easier to go for 'the right pill.' This is a big mistake; for example, when patient-related outcome measures were integrated into 'high tech' neurosurgery and treatment plans, there were measurable fiscal and psychosocial benefits (Pritchard et al., 2011). Similar results have been found for mental health (Kingdon and Turkington, 2000; Pritchard, 2006).

The public's perception of mental disorder has always been ambivalent at best. But the 'anti-psychiatry' movement was given a boost by the film *One Flew Over the Cuckoo's Nest*, which portrayed psychiatric care in hospitals as controlling via Orwellian misuse of language concerned only with control. The public's view combined with a political perspective led to the more legalistic Mental Health Act of 1983, in which the Psychiatric Social Worker (PSW) in adult psychiatry became the 'Approved Social Worker' (ASW), whose role was to be a potential brake and safeguard for patients and where possible, to minimize compulsory admissions. In addition, Community Psychiatric Nurses (CPNs) were brought into play; they were NHS-based, whereas ASWs were affiliated to the Local Authority. Over the next 20 years, there was a subtle shift

between the two roles. ASWs became more 'legalistic' and less supportive in the community and their role increasingly was taken up by the CPNs.

It is reasonable to assert that often public health policy is determined by a high profile case. For example in child protection, the tragedies of Victoria Climbe, (2001), Baby Peter Connelly (2007), and Daniel Pelka (2013), give the impression of a totally failed child protection service despite empirical evidence that child abuse-related deaths have never been lower in the UK since records began (Pritchard et al., 2013a). But the concept "naught is good or ill but as thinking makes it so" (Shakespeare, 1978: Hamlet, Act 2, lines 248–249) can be transposed in a modern world to "naught is good or ill but as the media makes it so"! The equivalent high profile case for mental health was Christopher Clunis, suffering from paranoid schizophrenia, who stabbed to death a total stranger, Jonathan Zito, on the London Underground in 1992. This triggered a wide media response, fueled the latent public prejudice about mentally ill people, and urged greater control of the mentally ill in the community. The media gave wide coverage to Mrs Zito who founded the charity The Zito Trust, campaigning for closer control and treatment of mentally ill patients in the community. This led to the 2007 Mental Health Act, which introduced 'Community Treatment Orders' (CTOs), which in effect compels mentally ill people in the community to take their medication, which Mr Clunis was not doing. Since this Act, the Zito Trust has been wound up, having achieved its objective (Bowcott, 2009). The hope remains of ensuring that the statistically very rare Clunis-Zito tragedy will happen even less frequently. This is not denying that violence occurs disproportionately more often with those who have psychiatric disorders. Yet, mentally ill people, (in part because of homelessness) are 4.9 times more likely to be homicide victims than people who do not suffer from this condition (Webb et al., 2013). Furthermore, psychiatric patients are at considerably higher risk of suicide and account for between 50 to 60% of the UK's annual average of 4200 suicides, i.e., psychiatric patients account for between 2100 and 2800 suicides a year (suicides greatly exceed the tragic toll of 9/11).

Overall, the MHA of 2007 (introducing the CTOs), has led to a more restrictive ethos. While there is value in seeking to ensure that people take necessary medication and improve contact with services, the increase in compulsion and its potential misuse remains an ethical dilemma. Conversely, mentally ill people have their lives shortened not just by self-inflicted violence, but also (in both adults and adolescents) by the accumulation of the side effects of psychopharmacological medication taken over years (e.g., Koelch et al., 2008; Gissler et al., in press).

The author recently worked with a grieving family whose daughter had died from cardiac and respiratory complications, aged 43, after years of medication for schizophrenia. Before her breakdown aged 22, she was tall and weighed less than 57 kilos. However, the latest new drug to better 'manage' her symptoms, increased her weight from 83 to 118 kilos in less than 18 months. That the coroner boldly included on her death certificate that she died of cardiac-respiratory failure to which the psychotropic drug had contributed; is a sign that the problem beginning to be recognized (e.g., Choong et al., 2012; Gissler et al., in press).

I am not advocating an anti-psychopharmacological position. There is real evidence of the lifesaving and enhancing benefits of appropriate, carefully monitored medication. Rather, I am highlighting the need for those working with people with mental disorders to understand the effects of the constant interaction of bio-psycho-social factors and to consider more actively the long-term effects of drugs.

In respect to CTOs there is some evidence from Australian studies showing that patients who have maintained better contact with social services have lowered readmissions or shorter lengths of stay because of earlier admissions (Kisely et al., 2013). However, an earlier Cochrane Review, Kisely et al. (2011) had concluded that patients on CTOs showed no significantly better use of service or improved social functioning. Yet, an important finding was that people on CTOs were less likely to be victims of violent crime (Kisely et al., 2011). More long-term research is required to be confident that the benefits of CTO outweigh the ethical dilemmas of compulsory treatment. The issue is to ascertain for whose benefit the CTOs are administered – patients, family, or society.

The social care component of Britain's multidisciplinary Community Mental Health Teams (CMHTs) has seen major changes. A CMHT aims to support people in the community, but these have twice as many CPNs than social workers, apparently because resources are restricted. The rate of ASWs per 100 000 population has doubled over the past decade (Huxley et al., 2005), which inevitably makes greater demands, especially during an economic recession. This might partially explain the ASWs low morale and sense of being undervalued, with higher levels of work-related stress (Evans et al., 2006). Furthermore, compared with the specialist indepth mental health training previously received by PSWs, current ASWs complain of the need for better training, especially in dealing with more severe cases (Walid and Wright, 2004).

Finding employment is a major issue for those with mental illness wishing to live independently. A recent study examined the use of the Individual Placement and Support (IPS) Model, to find that whilst IPS patients doubled their employment rate, but it still stood at only 22% (Heslin et al., 2011). This is a reminder of the vital importance of the 'social' element in the bio-psycho-social dimension that impacts the lives of vulnerable people.

Psychiatric Social Work in Child and Adolescent Mental Health

One area in which the counseling and supportive roles of PSWs continue in Britain is in Child and Adolescent Mental Health (CAMH) teams. These teams are usually led by a Child Psychiatrist, with Mental Health Social Workers (MHSWs) and Child Psychologists completing the interdisciplinary team. They work closely with schools and Educational Social Workers to provide more intensive psychosocial support services for children, especially those who have been neglected and abused and are Looked-After-Children (LAC), i.e., children requiring an alternative to family care. There is a long-standing concern about the psychosocial development of LACs, particularly if they were victims of neglect and abuse. Successive Acts have enabled these children to receive ongoing support up to

age 21; for those with special needs, support may continue for a longer time. There is considerable research about the poorer outcome of children leaving care (Stein, 2013), and CAMH teams are very active in supporting such young people (Stanley et al., 2005; Simkiss et al., 2013). Unsurprisingly, the outcomes for former LAC are significantly poorer than children who did not require local authority care. However, when former looked-after young men (aged 16–24 years) were compared with another group of relatively deprived children, who were former Excluded-from-School (EFS), the previous LAC men had considerably better outcomes than the EFS youth, who, unlike those leaving care, had no automatic social work support. It was the unsupported former EFS children who had significantly higher criminality, a murderer rate more than a 1000 times higher, and a suicide rate 100 times higher than their peers in the general populace. There were no murderers or suicides in the social work–supported LAC group, which is another indication that good social work works (Pritchard and Williams, 2009; Pritchard et al., 2014).

Two other big issues currently face CAMH social workers and society: Attention-Deficit-Hyperactivity-Disorder (ADHD) and Autism. Regarding ADHD, I worked in the three child guidance clinics covering the largest county in England, the West Riding of Yorkshire in the 1960s. Annually, there were fewer than two such children per clinic. Space precludes an adequate examination of ADHD, other than to say that it has inevitable disruptive psychosocial consequences, involving many child-related services. An examination of the online research database Medline shows the first paper related to ADHD, (then designated Minimal Cerebral Dysfunction), was in 1964. The hundredth paper was published in 1972. In October 2013, over a 1000 (1073) had been published, totaling about 16 737 papers since 1964. The debate still rages as to whether ADHD is linked to family disruption or underlying organic conditions. Meanwhile, drug companies have been very successful in offering a 'simple' chemical-based cure; they tend to ignore the *causes*, which are complicated by how families respond to their ADHD children (Dalsgaard et al., 2013). There is strong indicative evidence that changes in lifestyles and multiple environmental pollution contribute to ADHD. The related evidence comes from studies on the changing pattern of adult mortality. For example, whilst Western nations have been relatively successful in reducing aged-related adult cancer deaths, this hides the rising incidence of cancer across all age bands (Pritchard and Hickish, 2011). Another strong indication is the alarming increase in neurological morbidity and deaths, with dementia beginning a decade earlier, raising serious etiological questions about multiple environmental pollution, which is being increasingly linked to rises in the etiology of neurological morbidity as well as in ADHD and Autism (Pritchard et al., 2013b).

Could environmental pollution be a part of multifactorial causes of psychosocial problems in children? In 1968, Rachel Carson's seminal *Silent Spring* predicted that there would be a rise in 'irritant diseases.' These along with asthma and other immune disorders, with their associated psychosocial problems, are affecting Western children at an astonishing rate (Pritchard et al., 2011). This may seem unrelated to PSW but the importance of the bio-psycho-social model reveals that disciplinary boundaries need to be crossed to understand current problems and to challenge seemingly easy, short-term 'chemical' solutions.

In relation to Autism, Professor Leo Kanner first described the condition in 1944, suggesting it was an early form of psychosis caused by 'attachment failure' by parents, whom he described as 'refrigerator parents.' This provided an observation that attributed cause to untestable Freudian psychology, proving to be one of the worst misattributions in modern medicine – blaming parents without evidence (Pritchard, 2006). Even in the late 1960s, questions were being asked about Autism's possible neurological etiology. It is now recognized that the Autism spectrum is far more complicated. Broadly, it is a genetic-neuro-biological disorder that has cognitive and communication problems impacting upon the child's psychosocial development, and may be linked to an early manifestation of schizophrenia (e.g., Rutter and Sandberg, 1985; Howlin et al., in press).

The Psychiatric–Child Protection Interface

The third and most important aspect of the modern PSW is to understand the evidence-based concept of the child protection–psychiatric interface. This remains somewhat controversial. Early researchers emphasized that child abuse was an ubiquitous problem, crossing social classes and cultures; they largely ignored the psychiatric dimension, even as late as 1998 (Pritchard, 2004). For example, in the national confidential audit of violence and mental disorder, no mention was made of the age or relationship of the victims to the assailant (Webb et al., 2013), either because it was not initially reported or to avoid further stigmatization of mental illness being linked to child abuse. Yet, at the fatal extremes of abuse, the vast majority of assailants are predominately in a 'parental role' with many suffering from mental disorder. Consequently, with a few exceptions, the element of psychiatric child protection is unacknowledged (Falkov, 1996; Reder and Duncan, 1999), and this undermines effective treatment and child protection.

The psychiatric–child protection interface is far wider than just dealing with the potential extremes of 'abuse' and should focus upon the impact a parental psychiatric disorder has upon the child's development – an approach totally compatible with Britain's progressive *Every Child Matters* agenda. This demands that services relevant to children ensure that the five crucial aims for the child "being healthy, staying safe, enjoying and achieving, making a positive contribution, and economic well-being" are met (DCSF, 2005: p. 3). A greater awareness of the child protection–psychiatric interface could make the child safer and reduce the innate threat of removing a child just because there is a psychiatrically ill parent (Seeman, 2014). A better case-specific analysis could be made by recognizing potential risks – one psychiatric ill mother in 3000 goes on to kill her child (Pritchard et al., 2014).

Manfred Bleuler influenced my practice when he spoke of 'Children of Sick Parents.' I saw that older and teenaged children often had to 'care' for mentally ill parents, a fact that has been ignored until fairly recently. Fortunately, recent research is recognizing the children's need for help to cope with the "burden of mental disorder." Otherwise, without preventative services, they themselves are more likely to develop problems

as adults (Jensen et al., 2014; Seltzer et al., 2013; Viana et al., 2013).

A further element in the psychiatric–child protection interface is the link between child neglect and disproportionate levels of subsequent mental disorder as adults; neglecting parents themselves are often victims of an intergenerational cycle of neglect (Martorell and Zongrone, 2012; Buckingham and Daniolos, 2013; Sellers et al., 2013).

Social workers seeking to avoid being 'judgemental' seldom use a psychiatric diagnosis, in particular the concept of 'personality disorder,' which includes the judgemental sounding labels – psychopath or sociopath. Personality disorder is a useful concept because it highlights 'the persistent and characteristic' behavior of the parent who crucially does not appear able to care, lacking the core need to be altruistic and empathetic (Baron-Cohen, 2011; Brandon et al., 2012; Buckingham and Daniolos, 2013). Children with harsh parental behavioral patterns are at higher risk of becoming 'personality disordered,' perhaps best summed up by Macbeth's 2nd Murderer, "I am one whom the buffets and blows of this vile world hath so incensed I am reckless what I do to spite the world" (Shakespeare, 1978: Macbeth, Act 3, lines 106–109).

It is selfe-vident that we must not forget the vital importance of socioeconomic factors, as there is an overlap between relative poverty and psychopathology found throughout the Western world. Child poverty and poorer educational, health, and criminal outcomes, which are worse amongst children of poorer parents, compound the psychiatric situation (Palmer et al., in press; Pritchard et al., 2014).

Extremes of the Psychiatric–Child Protection Interface

After rare but tragic Child-Abuse-Related-Deaths (CARDs), there is massive negative media coverage, which raises the question, 'Who kills children?' In a study of a decade of CARD assailants who killed children from a 4% sample of the UK population, the initial work had sought to avoid further stigmatization of the mentally ill by focusing upon the differential levels of risk of the assailants, rather than on the frequency of those who killed the children (Pritchard, 2004). The latter focus showed that the majority – 12 of 18 (67%) – of assailants were within-family, and most had psychiatric problems (Pritchard et al., 2013). The study also revealed that all the blood fathers (4) committed suicide after the murder, as did two mothers; two other mothers had severe suicidal behaviors, quite apart from other mental health problems. The highest risk came from men with previous convictions for violence, both 'within-family' (4) and 'extra-family' (5), whose convictions heuristically classified them as Violent-Multi-Criminal-Child-Sex-Abusers. Their persistent, characteristic behavior over the years warranted the attribution of the 'severe personality disordered' tag (Pritchard et al., 2013).

Synthesis

Psychiatric social work is 'generic' in that people's mental health problems span all agencies and human behavior is a constant bio-psycho-social interaction. Edward Wilson has begun to integrate biology with the social sciences (Wilson, 2013) and has postulated, with evidence, the concept of a 'social gene.' This growing synthesis between what initially appeared to be contradictory theories is seen in Simon Baron-Cohen's seminal work (2011) that provides a superb evidence-based explanation of severe personality disorders demonstrating a bio-psychosocial etiology for Bowlby's Attachment Theory and explaining the absence of empathy in abusers.

Recent and current research highlights the need for an integrated bio-psycho-social understanding of, and preventative intervention for, people with mental health problems; and a better comprehension of the pediatric–child protection–psychiatric interface. Perhaps for the first time, at the national child protection level in UK, as mental health problems figure large in Serious Case Reviews, this message is beginning to be recognized (Brandon et al., 2012). Moreover, neuroscience research linking biological measurements, such as cortisol levels, with a range of environmental factors, (PTSD, maternal and socioeconomic disadvantage) has exploded in the past 10 years (e.g., Ehlert, in press; Koss et al., 2014; Palmer et al., in press), providing a biological understanding of problems, as well as recognition of the vital importance of child–parent attachment and constant bio-psycho-social feedback. The practice and policy implications appear self-evident:

1. Social work and the social sciences should rid themselves of the archaic notion of dualisms, such as mind versus body, nature versus nurture, dualisms.
2. Integrate the bio-psycho-social development model into human services as a range of preventative potential interventions. This could include biological measurements, such as cortisol levels, to measure stress reductions (Koss et al., 2014; Palmer et al., in press) that would improve psychosocial risk assessments and chart progress.
3. The policy implications are that pediatricians should overcome their recent reluctance to engage in potentially conflictual relationships with parents; accept their collaborative child protection role alongside children's services, education, and police; and recognize the interface with psychiatry.

Conclusion

In hindsight, while examining the case files of a decade of child homicides (Pritchard, 2004), if the adult psychiatrist had thought 'children – what is happening to them,' and if the child protection social workers had thought 'mental health' – then half the children who died would have been alive. This thinking should underpin the role of the modern mental health social worker, the professonal heir to the PSW. Encouraged by UK child-abuse-related-deaths being lower than ever (Pritchard et al., 2014), child-related disciplines could work even better together and be more preventative, not only in reducing child neglect, but in ameliorating the impact of parental mental disorder on children. By recognizing the importance and potential of the pediatric–child protection–psychiatric interface, within a family's socioeconomic context professionals can respond to the long-standing needs of 'children of sick parents.'

This article is a revision of the previous edition article by G.T. Harding IV, volume 19, pp. 13096–13102, © 2001, Elsevier Ltd.

Abstract

This article examines the changing relations between psychiatry and religion. It examines views of the causes and cures of mental illness in some religious traditions. Some psychiatric views of religion and its place in mental illness are described. Current psychiatric practice is examined, including areas such as ascertaining the patient's religious history, understanding cultural variations in religious behavior, and religious barriers to seeking psychiatric help. There is a brief overview of attempts to alleviate problems, including an outline of steps taken by professional organizations to accommodate the issues raised for psychiatrists by religious factors.

The relationship between psychiatry and religion has been difficult and variable, and has developed over the two centuries of psychiatry's official existence.

Psychiatry is the branch of medicine dealing with mental, emotional, or behavioral disorders (Merriam-Webster, 2013). For present purposes, it is significant that 'psych' is a stem of Greek origin often translated as 'soul' ('-iatry' refers to medical treatment). The term was first used in the early nineteenth century: this timing is significant since it reflects a developing medical interest in insanity, for which earlier there had been little or no treatment other than confinement under more or less (usually less) humane conditions. Current psychiatric views on the causes and cures of psychiatric disorder involve a huge range of detailed suggestions involving biological, social, and psychological levels of analysis.

Religion has many definitions and methods of assessment (e.g., Brown, 1987; Hill and Hood, 1999; Loewenthal, 2000). Major religions agree on the existence of nonmaterial (i.e., spiritual) reality, and see the purpose of life as increasing harmony in the world by doing good and avoiding evil. Monotheistic religions hold that the source of existence (i.e., G-d) is the source of moral directives. Religious traditions offer a range of views on the causes and cures of psychiatric disorders, and these often appear sharply different from the views offered in psychiatry, focusing chiefly on spiritual factors.

How have psychiatry and religion related to each other?

There has been a generally fraught history. Foskett (1996) describes it as a history of discord. This article will first examine how insanity and its causes and cures have been seen in selected religious traditions, and will then look at how religion has been seen through some psychiatric eyes. Finally, the current state of the relations between psychiatry and religion will be viewed, along with an overview of attempts to alleviate some of the problems.

Beliefs About Mental Illness in Different Religious Traditions

Psychiatry developed in the Western world at a time when Christianity was the dominant religion in Europe, the United States, and numerous colonial countries. Twentieth-century social and other changes have increased the numbers of Muslims, Jews, Hindus, Buddhists, and members of other (including new) religious movements in the Western countries. Religions have many different forms or denominations, with considerable variations in beliefs and practices. All have been and are in a constant process of development and change.

Christianity

The doctrine of the trinity (Father, Son, and Holy Spirit) is central to Christianity, as is the idea that the death of Jesus atoned for the sins of humanity. Important for mental health are Christian dogmas regarding sin. Suffering is the result of sin. Salvation involves justification, the removal of sin and its effects by one or more of repentance, penance, indulgence, confession, absolution, and forgiveness (e.g., Stagg, 1962). These doctrines may be associated with pejorative views of sufferers from illness and misfortune, including sufferers from mental illness (Lerner, 1980). It has been reported that Christians suffering from mental illness may be made to feel that their illness and suffering are the result of their sins (Stanford, 2007). However, although suffering is not seen as a desirable end in itself, it can be seen more positively as a gateway to renewal and rebirth. Some historians of psychiatry have suggested that a widespread Christian view of mental illness, particularly during the fifteenth to seventeenth centuries, is that it is the result of demonic possession (Lipsedge, 1996).

Islam

In Arabic, Islam means submission to the will of G-d. There is a clear core of religious duties, including belief in G-d and the prophets, prayer, giving away a proportion of one's goods, fasting in the month of Ramadan, and pilgrimage. In Islam, sin results from pride and self-sufficiency, leading to forgetfulness of divine unity and wrong moral/religious choices. An important Islamic view of the mentally ill is that they are the 'afflicted of Allah.' Some contemporary observers have noted that Jinn possession may be seen among Muslims as a cause of insanity (Dein et al., 2008). It is noteworthy that the earliest recorded psychiatric institutions – established over a 1000 years ago – were in Moslem countries (Loewenthal, 1994).

Judaism

Judaism is the oldest of the monotheistic religions, and a central tenet is the belief in the unity of G-d. There are many religious commandments, governing more or less the total lifestyle and practiced to varying extents: diet, sexual behavior, work, business ethics, and worship are among the areas of religious law. Madness is mentioned in the Jewish biblical texts without clear attribution of its causes, though there is some suggestion of a distinction between spirit possession and insanity. Later, Jewish sources of the Talmudic period distinguish a range of psychiatric conditions resembling those found in contemporary practice (Miller, 1972). The legal status of the insane with regard to their civil and religious obligations is a matter of discussion in works on Jewish law: for example, whether the insane are valid witnesses (probably not) and whether insanity is grounds for divorce (probably yes, but the situation is complicated). The Hebrew term for madness *(choli nefesh*) means sickness of the soul, and there are rabbinic figures in Jewish communities who carry out counseling and therapeutic activities based on views that the rectification of spiritual–moral failings – such as pride – will improve mental health. Misfortune is seen as warning to the individual to improve and as a divine test of the individual, also as part of an overall divine plan in which everything is for the ultimate good.

Hinduism

Hinduism is the religion of India and has many varied manifestations, tolerating a wide range of beliefs and practices. There is an underlying monotheism, with lesser divinities as aspects of one G-d. This infinite principle is truly the sole reality and the ultimate cause and goal. There is a religiously sanctioned caste system, said to be in some decline. Religious worship is carried out in a shrine in the home, usually by women. Transmigration of souls and reincarnation are important aspects of Hindu belief. The ultimate goal is infinity (G-d), and the attainment of this goal is prevented by *karma* (rebirth); following death and a sojourn in heaven or hell, the soul is reborn into a physical form determined by actions in the previous incarnation. This process of rebirth (*samsara*) is seen as potentially endless, and not progressive in any way. Misfortunes are an aspect of *karma*, and can be escaped by *marga* – emancipation – of which the main types are duty, knowledge, and devotion. Bhugra (1996) has described the importance of Ayurvedic medicine in the treatment of mental illness in India, and in one study, nearly half the psychiatric patients (81% Hindu) questioned had consulted a religious healer (Campion and Bhugra, 1997). Craissati (1990) states that mental illness in India carries a major stigma and that consulting a psychiatrist and going to the hospital are regarded as last and desperate resorts. In rural communities, where most of India's population (80%) lives, tolerance for bizarre behavior is very high. Psychotic symptoms are seen as the result of spirit possession or black magic, or as the consequences of a previous life. A mentally ill person will be taken to a healer within the community. If this is not successful, it is regarded as the family's duty to bear with the person. Craissati says that patients are only brought to the 'Western' psychiatric hospital where there is serious threat to the norms governing family life and sexual behavior.

Buddhism

The fundamental teaching of Buddhism involves viewing an attachment to the world and its pleasures as the cause of pain. Self-mortification is also an extreme to be avoided; the founder of Buddhism, Gautama Buddha taught the 'middle path.' Life is fundamentally a process of suffering. As in Hinduism, transmigration and rebirth are not seen as progressive, and the central aim of religious belief and practice is to liberate. The eight-fold path to freedom from suffering includes right thought, speech, action, and mental attitudes. These lead to the cessation of pain, and to enlightenment, and Nirvana (wherein the soul will not be reborn to further suffering). Buddhist psychology is popular in the West (Valentine, 1989). It is suggested that religious practices and thoughts will promote the relief of many if not all forms of mental illness and forms of meditation have been incorporated into contemporary cognitive behavior therapy (Segal et al., 2002).

Overall Religious Views on Mental Illness

This summary of views from selected religious traditions suggests that some similarities across religions can be seen. Beliefs about mental illness and its treatment may be tied to beliefs about sin and suffering, though malign spiritual beings may also be implicated. Mental illnesses are seen to result from separation from the divine or possession by evil. Psychiatry may be mistrusted, except as a last resort, and 'folk' healers may employ a wide range of symbolically loaded rituals and cognitive behavioral techniques designed to facilitate spiritual healing, leading (hopefully) to an improvement in mental health.

Some empirical work indicates that the views of religiously active people on psychiatric disorder will reflect religiously taught views – although in practice most of those questioned have a foot in both cultures, supporting both contemporary views on stress and biological factors, while simultaneously acknowledging the importance of spiritual factors (Cinnirella and Loewenthal, 1999; Leavey et al., 2007; Dura-Vila et al., 2011; Bayes and Loewenthal, 2013). Sin, however, is not a popular explanation among religious laity. In the Western world, the older generation of minority group immigrants may see orthodox health services and psychiatry as having little to offer. For example:

> … in the older generation if you've got a mental illness, they think you've got a bad spirit in you (and) that's why you hear all these voices and that's why this person (voice) is telling you to do things you've been doing … they'll just think, 'oh, go to a holy person and they will cure you.'
>
> Hindu informant, quoted in Cinnirella and Loewenthal, 1999.

Beliefs About Religion among Psychiatrists

Attitudes to psychiatric disorder change with time. In Western Europe and the United States, for example, one view of

disorder up until the eighteenth century was that it was caused by demonic possession, perhaps a result of the preoccupation with witchcraft from the fifteenth century onward, although stress was often seen as an important factor (Lipsedge, 1996). Fear, neglect, isolation, and ill treatment of the mentally ill were socially and religiously sanctioned. Bedlam in London and the Bicetre in Paris chained up their unruly inmates. The aim of such institutions was simply to isolate the unruly from society. Sometimes, the insane would be auctioned off to be 'cared for' (used as slaves) by farmers (Loewenthal, 1994). By the nineteenth century, medical opinion calling for more humane treatments was growing. Tuke, a Quaker merchant, founded the York retreat at the end of the eighteenth century. Here, prayer and religious devotion were seen as central to healing. Pinel and Connolly pushed the movement to see the insane as individuals suffering from sickness, requiring treatment. Pinel abolished chains from the Bicetre, and in the 1840s, Dorothea Dix began a campaign to improve conditions in institutions for the insane in the United States. Religious practice was often (but not always) acknowledged as an important feature of psychiatric care. In Britain the Lunacy Act of 1890 ordered a church in every asylum; inmates had to attend twice a day. In France, by contrast, Pinel would not allow the mentally ill to be exposed to religious practices: these might encourage delusions and hallucinations. Psychiatric hospitals in most Western countries nowadays normally maintain a chaplaincy service. This does not always cater for minority religions; chaplains are sometimes unpaid, and are normally overloaded.

Major changes in psychiatric thinking include the introduction of psychoanalysis in the early twentieth century, the anti-medical-model movement, the introduction of cognitive behavioral and other 'talk' therapies in the later part of the century, as well as the enormous growth in the neuroscientific and biochemical understanding of psychiatric disorder.

Psychoanalysis, spearheaded by Freud, carried as part of its baggage the general idea that religion was unnecessary and damaging to mental health. Four of Freud's books (1927, 1928, 1930, 1939) analyzed religion, reflecting and helping to form a growing *zeitgeist* that viewed religion as a collection of primitive superstitions, neurotic rituals, and an illusion, comforting at one time, but no longer necessary in these enlightened times. Freud described religion as a 'universal obsessional neurosis,' which has succeeded because it spares the individual the labor of developing his or her own neurosis. Freud described G-d as a projection of the image of the father, and "a system of wishful illusions together with a disavowal of reality, such as we find nowhere else but in amentia" (Freud, 1907, 1927).

Although Bettelheim (1983) attempted to see Freud's ventures as essentially spiritual in nature, and it is certainly true that religion was a major focus of Freud's attentions, Freud's writing has epitomized negative twentieth-century views on the role of religion in mental health. Other twentieth-century writers have contributed to this *zeitgeist*, perhaps most notably Albert Ellis in his earlier writings (e.g., Ellis, 1958). He was an outspoken participant in public debate, arguing that the influence of religion was to increase guilt and anxiety over wrongdoing: religion harmed mental well-being. His views on religion became more benign in later life (Ellis, 2004).

In contrast to Freud, Jung (1958) saw the psychological quest for wholeness and healing as a journey that is essentially spiritual. Jung's views were developed by others during the twentieth century, and were welcomed by those responsible for training clergy in pastoral work.

Contrary to Freud's and Ellis's claims, thousands of pieces of empirical work have by now shown that religiosity is normally associated with better mental health (Koenig et al., 2012). Nevertheless, there are still some lacunae: for example, the suggestion that religious ritual is compelled by anxiety has meant that very limited attention has as yet been given to the positive experiences and mental health benefits of the many religious rituals engaged in (Dein and Loewenthal, 2013).

The existence of a chaplaincy service can be a compelling reason for psychiatrists to feel that religious issues are for the chaplains to deal with: religious issues are outside the psychiatrist's competence and so are ignored (Neeleman and Persaud, 1995). Nevertheless, possibly related to the rise in popularity of the concept of spirituality, alongside the growing volume of work suggesting the importance of religious and spiritual factors in mental health, psychiatrists have taken a growing interest in religious and spiritual issues (Bhugra, 1996; Dein et al., 2011). Spirituality has been suggested as a possible contemporary alternative to religion (Heelas and Woodhead, 2005; King and Leavey, 2010; Dein et al., 2012), and contemporary psychiatric and social-scientific writing on mental health often feature discussions on its relations with spirituality as well as or instead of its relations with religion (e.g., Cook et al., 2009; Lewis et al., 2011; Paloutzian and Park, 2013; Pargament et al., 2013).

Views and practices about the place of religion in psychiatric theory practice have changed over the nineteenth and twentieth centuries. Generally, there have been growing numbers of attempts to integrate the role of religion into the understanding of the patient's psychiatric history, and to acknowledge the role of religion in treatment planning. The authors turn now to look at some specific aspects of contemporary practice.

Religion in Contemporary Psychiatric Practice

Some early signs of serious psychiatric interest in the role of religion in psychiatric care included conferences and publications dating from the 1990s (e.g., Bhugra, 1996; Loewenthal, 1994, Littlewood and Lipsedge, 1997; Greenberg and Witztum, 2001; Koenig et al., 2001). Some of this work was culturally limited (to practice in Christian-based Western cultures), but some emphasized the importance of acknowledging the importance of cultural factors and variations in the roles played by religion in different cultural religious groups.

There have been a growing number of claims that knowing the patient's religious history is important in psychiatric practice. Empirical work has suggested that many patients would welcome inquiries from mental health professionals about the place of religious and spiritual issues in their psychological battles, and there are useful published guidelines about how this may be done (Pargament, 2007; Koenig,

2008; Culliford and Eagger, 2009). Some of these suggestions have proved controversial. Notably, Koenig (2008) suggested that psychiatrists should take a spiritual history, support healthy religious beliefs and challenge unhealthy beliefs, pray with patients (in 'highly selected cases'), and work in liaison with trained clergy. The suggestion that psychiatrists are able to pass judgment on the healthiness of different religious beliefs and on the appropriateness of praying with their patients has aroused significant concerns (Cook et al., 2011; Poole and Higgo, 2011).

Barriers to seeking professional help for psychiatric problems are of major concern. These barriers often involve religious factors. Delay in help seeking can involve significant worsening of psychiatric illness.

These barriers chiefly involve fears of misjudgment, concerns about religiously inappropriate treatment, and fears of stigmatization.

Psychiatrists are less likely to be religiously active than their clients and this can heighten clients' mistrust (Bergin and Jensen, 1990; Cook, 2011), involving fears of professional misjudgment of religious behaviors, of which there are many examples (Loewenthal, 2007). Religious practices may give the appearance of bizarre behavior, which may be interpreted as mad, unreasonable, neurotic, selfish, or heartless. For example:

> The concept of a 'good death' is very important to Hindus. A good death involves making spiritual preparation for the soul leaving the body, and settling ones worldly affairs. One of the religious customs which many Hindus feel should be observed is that when death occurs, the person should be lying on the ground, preferably in a certain orientation with respect to the north. This has led to many difficulties with Hindu patients in British hospitals. Many will make efforts to be at home if and when they feel the end is approaching. When the dying person is in hospital, he or she may manage to climb or roll out of their bed in order to be on the floor for the moment of death. This obviously requires tremendous effort, but it is often wasted, especially if there are no relatives or friends to explain the meaning of the behaviour. The horrified nurses rush over to replace the nearly moribund patient safely back in bed – much to his/her distress. Their sufferings are increased when their pleas and protestations are not effective, and every time they manage to assume the religiously proper position on the floor, they are firmly bundled back onto the bed. The first time the patient appeared on the floor, the nurses might have thought it was a mishap of some kind, but after the third or fourth time, they thinks/he is deluded, mad, or deliberately being a nuisance.
>
> Firth, 1997

The fear of misjudgment constitutes a barrier to the seeking of professional help for mental health difficulties. Judgment biases have sometimes been demonstrated empirically. For example Yossifova and Loewenthal's (1999) vignette study involved clinical judgments of case histories identical in every detail except that some patients were described as religiously active, while others were not. Religious people were more likely to be seen as suffering from obsessive illness than nonreligious people with the same symptoms.

A further barrier is the fear that treatment recommendations may be seen as religiously inappropriate. Some religious groups will avoid psychotherapy if there is a risk of physical contact between the sexes (Loewenthal, 2006). Those from collectivist religious cultural groups may feel that professional suggestions to alleviate distress and psychiatric symptoms by leaving abusive relationships may be rejected on the grounds that family and community solidarity is more important and religiously valuable than individual well-being (Gilbert et al., 2004; Loewenthal, 2013).

An associated, stronger barrier is the extent to which mental illness is stigmatized, and this effect may be particularly marked in tightly knit social groups, of which religious groups are an outstanding examples:

- Our people do not go to the doctor (when depressed), in fact they hide it, because they think that if people know about it they will not accept them and they'll be laughed at and would be completely shut off because there is this prejudice (Muslim, in Cinnirella and Loewenthal, 1999).
- The one thing Black people hate is for anybody to find out there is any form of mental illness in their families … what they try to do is shut that person away and deal with it by themselves as opposed to going through all the networks and being exposed. (Black Christian, in Cinnirella and Loewenthal).
- I wonder what type of families need this (kind of help)? Is it just those who can't cope? I might feel ashamed to ask for such help (Orthodox Jewish, in Loewenthal and Brooke-Rogers, 2004).

Examples of recent work in the field give further indications of some of the issues preoccupying investigators. Regan et al. (2013) systematically reviewed the literature showing how religion influences pathways into care for dementia patients in minority ethnic groups. The main conclusions were that religion hinders access to the traditional care for dementia, which may increase the burden on relatives and other carers. For example an African-American woman, a Pentecostal Christian, filled with the Holy Ghost in a nursing home became excitable and fainted. Her behavior was misinterpreted as pathological and she was unnecessarily restrained. Reports of such incidents lead to fear of misunderstanding, and delay care seeking. However, Regan et al. conclude that religion, as in other areas, assists carers in positive coping.

Another recent study (Dura-Vila et al., 2013) examined the accounts of coping by contemplative nuns who had been sexually abused by priests. Trauma was "transformed into a symbolic religious narrative" in lengthy processes of solitary introspection involving forgiveness, sacrifice, and salvation, which reshaped their core beliefs and allowed the abused women to regain their sense of spiritual well-being: for example, the postabuse contemplation eventually led to an increase in the sense of spiritual purity. This work contributes to the growing literature on posttraumatic spiritual growth, and on positive psychology, important elements in the psychiatry–religion interface.

Improving Practice

From within religious groups, clients see therapists from their own religious group as more likely to understand them.

However, they can be worried that this makes it more likely that their problems will become known in the group (Cinnirella and Loewenthal, 1999; Loewenthal and Rogers, 2004). One solution is the provision of own-group help in discreet locations, in which the client feels less concern about being seen by people they know. Further, clients may select own-group helpers belonging to a social subgroup different from their own. Attempts have been made to train own-group professionals, particularly in counseling skills – clients may still have concerns about the professionalism and confidentiality, but on the whole such training schemes have worked well and have filled a gap in service provision (Loewenthal and Rogers, 2004).

Attempts to improve awareness of mental health issues, and of ways to manage them, include dissemination of information via various media including the Internet (for example, the American Psychiatric Association Web site (2013) offers a wide range of mental health information for the lay public, as does the UK Royal College of Psychiatrists Web site (2013)), offering 'Mental health information for all.' These attempts may help to reduce the strength of some religiously related barriers to professional help seeking.

Professional organizations have been active in improving training to increase awareness and knowledge of norms of relevant religious behavior. An important step taken by the American Psychiatric Association was to introduce the V code into the fourth edition of its internationally used diagnostic manual; this was a significant attempt to depathologize religious behavior, and to alert professionals to the possibilities and methods of distinguish normative from pathological religious behavior (Scott et al., 2003; Dein et al., 2011). Significant books contribute to awareness of this issue (e.g., Bhugra, 1996; Peteet et al., 2011). The UK Royal College of Psychiatrists Special Interest Group focusing on spiritual issues in psychiatry, the UK National Spirituality and Mental health Forum, and other bodies organize conferences and publications (Royal College of Psychiatrists, 2013; National Spirituality and Mental Health Forum, 2013), with significant focus on the importance of religious issues in diagnosis and treatment. There are several academic journals featuring research and thinking on the psychiatry–religion interface (notably *Mental Health Religion and Culture, Transcultural Psychiatry, and The International Journal of Social Psychiatry*). In related disciplines, Division 36 of the American Psychological Association focuses on the psychology–religion interface, and several journals contribute to the understanding of social-scientific perspectives on mental health issues (for example, *Anthropology and Medicine, Journal of Religion and Health, International Journal for the Psychology of Religion, and Social Science and Medicine*).

There has been a useful growth in the volume of work designed to improve understanding of the interface between psychiatry and religion, for both professionals and laypeople. There is scope for more, perhaps particularly for further attempts to improve understanding of mental disorder among laypeople, to reduce the stigma associated with this disorder, to reduce the negative impact of religious factors, and to allow scope for the positive roles that can be played by religion in coping with psychiatric disorders.

Psychiatry: Anthropological Aspects

Alfred Kraus, Centre for Psychosocial Medicine, University Hospital for General Psychiatry, Heidelberg, Germany

Published by Elsevier Ltd.

Abstract

Psychiatry today understands itself empirically to a far-reaching extent, as a science of facts of various methods. In its medical practice, being related to the whole mentally ill human, the question is put as to how far scientific methods are related to the whole being of a human, that is, to anthropological aspects and in which way these are guiding scientific research.

Various kinds of anthropologies have implications for medicine, particularly for psychiatry and psychotherapy. Most of these anthropologies are latent and not always easy to determine. These are, however, also anthropological approaches that are related to a certain kind of pioneering anthropology.

Along with the separation of natural and cultural sciences, we have to discriminate between anthropology in the sense of natural sciences and philosophical as well as cultural anthropologies. Biological anthropology, identical with physical anthropology, or human biology, is concerned with the biological nature of humans. In contrast to or supplementary to this, philosophical anthropology refers to statements about the personal or spiritual essence of humans. Cultural anthropology, mostly interchangeable with ethnology comparing different cultures, is concerned with the question, 'What is variable or constant in human beings in different cultures?' Transcultural psychiatry relates to cultural anthropology. All of these anthropologies can have a relationship to psychiatry in one way or another. Some approaches in psychiatry can conceptually have a stronger and explicit relationship to a certain kind of anthropology. We will be concerned here mainly with these approaches in psychiatry.

From a methodological point of view, we can speak of two main perspectives in psychiatry: a natural–scientific one and a hermeneutical one (hermeneutical not in the narrower sense). In some way, both these perspectives can be conceptually and methodologically opposite or supplementary to each other. The natural–scientific perspective relates to laws, and the other perspective relates to reasons (e.g., such as motives). The natural–scientific perspective limits the experience to what is repeatable, measurable, and calculable. It strives to eliminate the subjectivity of the patients. The hermeneutical perspective is mainly concerned with the subjectivity of the patient, his/her personal situation and history, and with his/her unique inner experiences. A basic task of every kind of anthropology is, or should be, to determine in which respect humans are different from any other kind of being, particularly from animals, and how far anthropological statements are universally valid. All these questions are fundamentally important for all concepts of mentally ill persons.

The most important influences on psychiatry have emanated from different orientations of philosophical anthropology. Questions such as 'What mental illness is in its various manifestations?,' 'Which methods of investigation and which kinds of therapies are adequate to mentally ill patient?,' and 'Which method is ethically justifiable?' were in different cultures and in different historical epochs, as well as they are now, to a high degree dependent on the respective conception of human beings. In different ways, the various approaches determine the border between the pathological and the normal state, between illness and health. This is to a very high degree dependent *on* basic philosophical assumptions about the nature of humans, as, for example, the relationship of body and soul, of biological and sociological determinations, of human heteronomy and autonomy in general. Because psychiatry as a science as well as a therapeutic practice latently always implies an anthropology, it cannot avoid reflecting on these premises. The respective anthropology has an influence upon what in psychiatry can become a scientific object and by which methods this object is accessible. Thus, basic anthropological assumptions on the one hand not only promote the development of certain approaches of psychiatry but on the other hand they may also prevent the development of others.

Considering a certain mental disorder under anthropological aspects, or under the aspect of the relationship of certain dimensions of human beings, can have consequences for a widening development and refinement of our modes and methods of making experiences with our patients. The experiences of the patients might be very strange to us, and make it difficult for us to emphasize with them.

From a philosophical point of view, the most fundamental question of anthropology is, 'To what extent is it possible to start with a previously given essence of a human being and in which way is the human being incomplete, "an open possibility" (Jaspers 636) in what he/she is?' This question became one of the main topics of existential philosophy: 'How far can it be determined what man is in his essence?'

Some anthropological approaches tend to a comprehensive foundation of medicine, sometimes with a danger to idealize certain approaches in medicine (Schmidt-Degenhard, 2002). In contrast, anthropological approaches can be very reductive, and empirically lead to nothing but theory.

What Jaspers said about philosophy in general is also valid for anthropology. He stresses its significance for psychiatry; it does not only free the inner space for new possibilities of knowledge but it can also open up horizons that are more adequate to a better understanding of the patient. A switching between anthropological and empirical research (Mundt and Spitzer, 1999) has a decisive significance for innovation and thus for the development of psychopathology as well as psychiatry in its therapeutic and rehabilitative practice.

Immanuel Kant ([1798]1978) was one of the first philosophers who explicitly formulated a philosophical anthropology. He differentiated between a physical and a pragmatic anthropology. Although the first one is concerned with what humans are by nature, the second one, identical with philosophical anthropology, asks what they can make out of themselves. Kant's philosophy became important for psychiatry not only because he developed interesting ideas about mental illness, seeing its general features in a loss of communal sense (sensus communis), that is, the loss of the ability of a person to be corrected by others (§ 53, p. 117), but also especially because he has influenced psychiatry with respect to its methodology. Showing the dependency of experience on a priori ideas and thus overcoming the traditional splitting of subject and object, Kant's philosophy ([1781/87]1965) stood for an opposition of idealism to realism, which maintains the independence of recognizing the subject from the object. This opposition has had a constant effect not only on many philosophical schools of thought but also on psychiatry. With his concept of the transcendental subject, he paved the way for Husserl's phenomenology and for existential approaches of philosophy. These new concepts and methods on their part made possible approaches such as *Daseinsanalyse* and existential psychoanalysis, existential psychiatry, and cognitive approaches. Because above all in psychoses the comprehension of the world by the experiencing subject has changed, these psychiatric approaches claim to provide a better understanding of the cognitive processes in these patients.

The following authors of a philosophical anthropology have become important in psychiatry: J.G. Herder (1744–1803), for emphasizing the human as a being gifted with language; G.W.F. Hegel (1770–1831), for his historical philosophical critique of anthropology; M. Scheler (1874–1928), for being the founder of modern anthropology in his work *The Place of Man in the Universe*; H. Plessner (1892–1985), for speaking of the eccentric position of human beings, who have to realize themselves what they are; and A. Gehlen (1904–67) for his determination of human beings as being deficient because of their lack of adjustment to their surroundings and their reduction of instinct. At the same time, an openness to the world corresponds to this lack.

For a psychiatry that calls itself anthropological, the following philosophers were above all influential: S. Kierkegaard (1813–55), who initiated the development of existential philosophy; E. Husserl (1859–1938), who was the main founder of the phenomenological approach in philosophy; M. Heidegger (1889–1976), who put forward Daseinsanalysis; J.P. Sartre (1905–80), who proposed existential psychoanalysis; and M. Merleau-Ponty (1908–61), who put forward his phenomenology of the body. However, there has also been an influence of medicine, especially of psychiatry, on philosophical anthropology: here, we could mention Heinroth (1773–1843), V. von Weizsäcker (1886–1957), and L. Binswanger (1881–1966).

Multiple influences on psychiatry also arose from biological anthropology (including paleoanthropology, human genetics, and research on human bodily constitution), from social and cultural anthropology, from cognitive and evolutional anthropology. Social anthropology and role theory (Kraus, 1980) had a strong impact on the development of social psychiatry and antipsychiatry, followed by many psychopathology concepts and therapeutic measures.

Cultural anthropology examines the cultural variation of the human being compared to human constants independent of culture and epoch and very clearly shows the double significance of the concept of anthropology already mentioned above. It shows the variability of the actual being and behavior of human beings and at the same time marks the boundaries of anthropology as a universally valid theory of the essence of humankind. Cultural anthropology has cultivated a special approach of a transcultural or cultural psychiatry, which investigates the variability and frequency of symptoms of disturbance entities, nowadays defined in glossaries, as well as of these entities themselves in different cultures. It has also led to the question whether regarding the classical entities of disturbances such as schizophrenia and manic-depressive illness we are actually dealing with entities of natural diseases, or whether these are entities coming from concepts of understanding. Transcultural or crosscultural psychiatry is thus fundamentally involved in the contemporary crisis of nosology in psychiatry.

With the notion of a cognitive anthropology, Emrich and Schiefenhövel (2001) sum up different approaches of psychological, physiological (Singer, 1994; Roth, 1994), and philosophical constructivism. In cognitive anthropology, the leading idea is the general quality of constructivity ascribed to systems generating consciousness (Roth, 1994). The progress of modern evolutional biology could in the future enable a phylogenetic and ontological understanding of mental disturbances.

Heinroth can be looked at as the founder of an anthropological medicine in its true sense in the context of psychiatry, not to be confused with a medical anthropology. Many anthropological approaches in general medicine, especially those of Weizsäcker and Wyss, have also had effects on psychiatry.

Janzarik (1988) has presented an approach of his own to anthropological psychiatry. In his structural–dynamic concept, he sees psychopathological phenomena in their neurobiological (dynamic) foundation as coherently connected with biographical, structurally bound significances.

Kick (2004, 2005, 2009) has dealt with ethical and anthropological questions, and has compared therapy and marketing of healthiness, such as material goods, by seeing the therapist as a therapeutic manager and the patient as a client. He also tested dilemmata of anthropological premises in borderline situations such as prevention of suicide and medical assisted suicide.

Schmitt (2003) investigated the old anthropological model of diet and ethical questions with respect to the progress of research. Schmitt (2010) stressed also reconciliation as the aim of psychotherapy.

Schmidt-Degenhard (1997, 2002) has given several instructive overviews on the phenomenological–anthropological approach in psychiatry. Schmidt-Degenhard (2000) contributed much to the differentiation of the illusion of the imagination, fiction, and the oneiroid.

Mundt (1989) pleaded for an alternation between a hermeneutic–holistic view and an empirical–alienating objectivation. Mundt and Spitzer (1999) opined that cognitive neurosciences overcame the dualism of these methods by integrating

biological function and subjective experience. Mundt (1989) and Mundt with Spitzer (1999) gave overviews on contemporary psychopathology. Applying the notion of intentionality, Mundt (1984, 1991) developed a new understanding of syndromes of deficiency and other syndromes in schizophrenics. Mundt and Fuchs (2002) dealt with an interaction of objectifying methods and holistic experiences under the aspect of anthropological phenomenology.

Under the heading of phenomenological–anthropological psychiatry, different approaches can be summarized, which have a phenomenological method and an anthropological orientation in common. Psychiatrists, psychologists, and philosophers of this approach are among others: In Germany: v. Baeyer, Blankenburg, Bürgy, Feldmann, Fuchs, v. Gebsattel, Häfner, Kisker, Kraus, Lang, Müller-Suhr, Schmidt-Degenhard, Tellenbach, and Wyss. In France: Charbonneau, Naudin, Pringuey, and Tatossian. In the United States: Hersch, Schwartz, Straus, and Wiggins. In Italy: Ballerini, Callieri, Calvi, and Stanghellini. In Denmark: Parnas and Zahavi. In Switzerland: Holzhey-Kunz. In Chile: Dörr-Zegers and Figaroa. These psychiatric approaches of an eidetic phenomenology of essence and of a phenomenology of constitution as well as of daseinsanalysis and existence analysis relate to different authors of philosophical anthropology in its broader sense such as E. Husserl, M. Heidegger, J.P. Sartre, and M. Merleau-Ponty.

Even if the understanding of phenomenology and phenomenological in these different approaches is not always the same, the notion of phenomenon aims at that 'which-shows-itself-in-itself' and as such is different from the notion of the symptom, which points to something that does not just show itself directly, namely, to the illness underlying it. An approach strongly oriented to the phenomenon enables us to describe the original individual subjective experience as well as the respective life world of the patient more adequately and in more detail than is otherwise possible.

'Anthropological' signifies on the one hand what is common to all people and on the other hand what in contrast to the animal is specifically human. In the context of anthropological psychiatry with this term, the relationship of psychiatric disturbances to basic human structures is meant, as, for instance, consciousness and subjectivity, intersubjectivity and individuality, history and temporality, freedom and corporality. These approaches not only take into consideration human essence because of ethical or humanistic reasons but above all they consider methodological reasons. The aim is to understand psychiatric disturbances as regular variations of these basic structures that means of human essence itself. This is done not so much to investigate the factual conditions for the development of psychopathological phenomena but to investigate the conditions originating from human essence, which made them possible. For instance, hallucination can be understood out of the normal act of perception as an uncoupling of spontaneous imaginative acts from a normal interaction with receptivity (Blankenburg, 1980a,b).

Binswanger's (1955) concept of 'anthropological proportion' has turned out to be especially fertile in psychiatry. The partly oppositional dimensions of height and breadth in human existence, of self-realization and world realization, of individuation and relationship to community, of need for continuity and openness to innovation, of tolerance and intolerance of ambiguity, of overidentification and underidentification normally stand in a certain proportion to each other. These proportions are shifted in psychiatric disturbances. Relating to this alteration of the respective proportions, some pictures of illness are oppositional. Thus, an overidentification with their respective being in melancholics can be opposed to an underidentification in hysterics (Kraus, 1996a). Overidentification with the social role, for example, with the environment, can understandably precipitate a melancholic phase in the case of their loss. One speaks of an empty-nest depression, if a parent becomes depressed when children leave home. Other examples are depression in the situation of retirement or of relocation. Hysterics, on the contrary, tend rather not to identify with their respective being or their actual feelings. They are striving to be more and something different than they actually are, or to show feelings they do not have. The abnormal as well as the normal can in this way be located in a polar field that is structured through ideal norms that oppose one another in a field where 'deviations' from at least two sides are possible, as Blankenburg (1980a) put it. The pathological element can in this way be traced back to healthiness. On the other hand, healthiness shows itself as something that always holds the possibility of becoming pathological by an alteration of proportions.

Such a concept of mental disturbances offers a special possibility of identification with the patient in the therapeutic process. Beyond a purely descriptive psychopathology in the sense of Jaspers (1965), it is thus possible to develop a dynamic phenomenology of psychiatric disturbances that has a dialectic character. Jaspers in his subjective psychopathology emphasized the special experience of the patient as opposed to a mere behavioral description in the sense of an objective psychopathology. Assigning Jaspers to the phenomenological–anthropological approach is sometimes disputed, because on the one hand he was one of the most important promoters of this approach with many of his ideas and concepts, but on the other hand, he was very critical of the application of philosophical anthropology in psychiatry and had a very restrictive understanding of phenomenon, identifying it with symptom. Later on, he was more sympathetic with this approach.

An eidetic essence-oriented phenomenology described above goes a step further in trying to grasp the essence of altered experiences and behavior in a so-called eidetic reduction in the sense of Husserl. In a process of free imaginative variation, one tries here to pass from a fact to the essence of a fact, from a sensual to a categorical presentation. Categorical presentation means, for instance, to recognize a particular species of tree in an actual tree, or in different kinds of behavior and experiences of hysterics the element of underidentification, of the pretense of being instead of actual being. Such an eidetic reduction can also be carried out in relation to Heidegger's notion of '*In-der-Welt-sein*' or Merleau-Ponty's '*Être-au-monde*' to show the special relationship of patients to themselves and to the world, which is expressed in their experiences and behavior. A constitutive or transcendental phenomenology in the sense of Husserl should be differentiated from an eidetic phenomenology. Instead of passing from the fact to the essence of a fact as

in eidetic phenomenology, constitutive phenomenology examines the constitutive achievements of consciousness, which lets us perceive the concrete as it appears to us.

This approach of a constitutive phenomenology and the following philosophy of existence became important for psychiatry, because in the perception of psychotic patients – but not only for them – the world and its significances constitute themselves in another way than in healthy people. In psychiatry, this resulted not only in making the experience of objects, for instance, classical symptoms, into a research topic, but also the preobjective experience, that is, the constitutive processes out of which self and world develop. The particular method of constitutive phenomenology so called epoché, that is, putting all judgments of reality in brackets by refraining from it. This is particularly important for the diagnostician and the therapist for being open as much as possible for the often extremely strange world in which psychotic people live and to transcend in their world. Not only to judge patients insofar as they deviate from the norms of normality but from their being-in-the-world is one of the most important advantages of the phenomenological–anthropological diagnostics.

The preobjective experience is especially important in the intuitive diagnostics, for instance, in the so-called precox feeling. Such preobjective experiences are, for instance, the spatialization, temporalization, intersubjectivity, and corporality of a patient. Classical symptoms and concepts, such as delusion, hallucination, phobic anxieties, and obsessive–compulsive symptoms, assessed by a psychopathology oriented to the object turned out to be constructed on such preobjective experiences.

Phenomenology of constitution, as Husserl put it, has recently entered into a manifold relationship with cognitive theory and cognitive neuroscience (Wiggins and Spitzer, 1997; Gallagher, 1997). Varela (1996) even proposed a neurophenomenology. The main problem of such attempts is that these very different methods have a completely different understanding of what the notions of evidence in both methods mean. Evidence in the phenomenological–anthropological approach is not identical merely with plausibility. Several authors of the phenomenological–anthropological approach showed how in the contents of delusion and hallucination versus the psychotic tendency of dissolution of their world patients try again to give sense to their new world, even if a distorted one (Feldmann and Schmidt-Degenhardt, 1997; Müller-Suur, 1980; Kraus, 1994a).

Husserl's concept of an intersubjectively constituted life world has become increasingly important for psychiatry, above all for the understanding of schizophrenic modes of existence (Callieri and Castellani, 1981; Blankenburg, 1979). People with schizophrenia are characterized by a damaged rootedness in the life world, connections of significances and relevancies becoming confused, which shows itself in extravagance and oddity and also in the delusions of these patients. Blankenburg (1971) speaks of a lack of natural self-evidence in schizophrenics. Although schizophrenics often lack an inner standard that would allow them a behavior appropriate to the social norms, melancholics – being too adapted to these norms – are too strongly fixed and to their lifeworld to common sense (Blankenburg, 1979; Stanghellini, 1997; Kraus, 1996b). This is already shown premorbidly by their hypernomic behavior, which is characterized by a lack of distance to normative expectations (Kraus, 1996b). It is also shown by the fact that they find their identity above all in their social roles. For this reason, they are especially in danger of becoming depressed in the case of the loss of a social role (Kraus, 1996b; see below).

Binswanger has developed his 'Daseinsanalyse' (not to be confused with '*Daseinsanalytik*') above all under the influence of Heidegger's '*Daseinsanalytik*' in *Being and Time* (Heidegger, 1963), which, against the ontological intention of the author, Binswanger understood as an anthropology. With 'Daseinsanalyse' we are concerned with a hermeneutic of the inner life history, which is asked for its underlying individual concept of the world determining the concrete experience and behavior of a person.

Sartre's (1962) existential psychoanalysis has also contributed to a better understanding of certain pathological modes of existence such as those of hysterics, melancholics, and patients with anxiety and obsessive–compulsive disorders. In this way, we can establish certain existential types, which can have an impact on the classification of these disorders (Kraus, 1994b).

Partly as a reaction to the philosophy of consciousness of Husserl, and also following the late Husserl, the philosophy of the twentieth century was very much determined by the topics of a phenomenology of the life world and of the body (e.g., Merleau-Ponti (1965), H. Schmitz (1964–78), B. Waldenfels (2000)). For Husserl, the life world became particularly important for the foundation of scientific knowledge in everyday life experiences, that is, in pregiven matters, in sedimented experiences of generations. This became important, for example, in the understanding of schizophrenia under the aspect of an so called 'loss of naturalness' (Blankenburg, 1971).

It was particularly Merleau-Ponti (1965) who showed how our relationship to the world is determined by our bodilyness, that we have world only through our bodilyness. Thus, our world is always already a world interpreted by our bodilyness. Our body has so its own valid sense, its own understanding of the world already before we are an ego. This becomes particularly apparent in the kind of schizophrenia characterized only by certain bodily symptoms, in an so called coenesthetic schizophrenia (Kraus, 2011).

Here as well as in other psychiatric disorders, for example, in melancholia, Dörr-Zegers and Tellenbach (1980); Fuchs (2001); Kraus (2002) spoke of a corporealization, a coming to the fore of the physical corporeal body, which is normally as a lived body more or less tacitly transcended (Sartre, 1962). In the melancholic state, the body loses its capability of resonance in front of the environment (Fuchs, 2001, 2005). Because of this corporealization, a general kind of depersonalization (Fuchs, 2001; Kraus, 2002) may appear. Phenomenological–anthropological psychiatry is not so much interested in the deviant behavior as such of patients, but with the possibility to behave in one or another way. Thus, freedom is a prominent topic of this approach. Because forensic psychiatry has mainly to do with the question of an incapacity to behave in accordance with social norms, the phenomenological–anthropological approach is also of significance in this field. Tatossian (1996) was right in saying that

operational criteria are not sufficient, when it comes to assessing the capacity of a patient to act freely.

There are two fields of present psychiatry where anthropological therapy and contributions are particularly important. These are diagnostics and classification as well as psychotherapeutic treatment and rehabilitation. Already the notion of illness in psychiatry is so different from that in somatic medicine that it may be asked, whether it has to be anthropologically complemented (Wyss, 1973, 1982) or reformulated. According to Jaspers (1965), in psychiatry, we have to discriminate between disorders with a known somatic cause, called species (Gattung) and such disorders without a known somatic cause that Jaspers called ideal types (Idealtypen). Ideal types are constructs won by thinking intuition as an ideal typical coherent whole. Schneider (1967) took this notion of type from Jaspers saying that with schizophrenia and cyclothymia, we do not have to do a diagnosis in the medical sense but only with two types of mental states. Because symptoms and disorders here have a different logical structure, he spoke of criteria instead of symptoms. The glossaries of diagnosis and classification of Diagnostic and Statistical Manual of Mental Disorders (DSM) and International Statistical Classification of Diseases and Related Health Problems (ICD) did not follow this way of Jaspers and Schneider but returned to Kraepelins' concept of these two psychoses as somatic illnesses, the notion of criterion here having a different, only an operational meaning.

The mentioned present manuals of diagnosis and classification were on the one hand seen as a great success, but on the other hand they have also been criticized. A biological psychiatrist wanted the criteria of the respective entities of disorders in their description to be more functionalized (van Praag, 1996; Gaebel, 1996), so as to let the classification entities appear as disturbance entities of some functions.

A team of the World Psychiatric Association called International Guidelines for Diagnostic Assessment (Mezzich and Ustum, 2002) proposed that the amendment of the manuals should be more oriented to the whole person of the patient, instead of seeing him only as the bearer of an illness. Different from the present reductionist manuals, these should be combined with a standardized, multiaxially personalized ideographical recording of the respective patient. Humanistic and ethical demands should be taken into account, and a prototypical categorization is requested.

All these aims are very similar to those of a phenomenological–anthropological psychiatry. From this point of view, a phenomenological–anthropological diagnostics and classification could be developed, complementing the symptomatological–criteriological one, as we proposed in some articles (Kraus, 1994b, 2003). The last one is mainly oriented to the morbus of the patient (in the sense of having a disease, e.g., having schizophrenia), the phenomenological one is holistically oriented to the person of the patient and his lifeworld (in the sense of being ill, e.g., of being schizophrenic). Consequently, in the symptomatological–criteriological diagnostics, we have to do with symptoms in the phenomenological one with phenomena. Phenomena are then not understood as identical with symptoms but mainly in the sense of eidetic and constitutive phenomenology and daseinsanalysis.

In the diagnostic manuals, disease entities are conceived as existing in reality, as being ontological realistic in nature. Here, disease entities and symptoms are taken as facts. It is not considered that these facts are loaded with meanings and values that incorporate cultural bias toward these entities and their symptoms (Fulford, 1989, 2005; Moij, 2012). The manuals conceive of a mental disorder as a direct consequence of a deficient or disturbed cerebral structure (Moij, 2012) that causes some dysfunction. The criteria of the disease entities are principally elementaristic, without a unifying sense. Behavioral aspects, not the experience of the patient, are in the foreground. The reliability of the criteria is taken as being more important than the validity. In the phenomenological–anthropological diagnostics and classification the classificatory entities can be seen as existential types (Kraus, 1994b) of modifications, or basic existential structures of being-in-the-world and being-with-others. Daseinsanalytic authors would speak of an orientation to the ontologically meant 'existentials' of Heidegger. Here, the methodological focus is on the individuality, subjectivity, historicity, temporality, spatiality, the embodiment of the schizophrenic, the manic, and the melancholic patient. All these phenomena are unified in a certain structure of the respective existential type in the sense of a psychopathological organizer, as Rossi Monti and Stanghellini (1996) put it. Thus, for example, schizophrenia, mania, and melancholia are seen as certain modifications of the being-in-the-world and in this way anchored in the essence of a human. Even if the existential types are not primarily oriented to the morbus entity, but to the being-in-the-world of the patient, they can be of important heuristic value for the finding of disease entities. Their particular value is that the guidelines and norms of psychotherapy and rehabilitation result immediately from the respective existential type, that is, from the diagnostic process itself.

In the following, we will deal with the procedure of a phenomenological–anthropological diagnostics and its significance for the therapeutic measure in the case of patients with a manic-depressive disorder, which we see as a kind of identity disorder. Before we can do this, we have to start from a concept of human identity that should not be confused with that of the identity of things. Instead of a concept of identity as a substance with certain qualities, we need a concept of identity that allows for developing oneself, that is, for identifying oneself with certain representatives of identity and also for giving them up, dissolving these identities in the course of life. Such a kind of identity is, for example, provided by Mead (1980), which we take over.

We will demonstrate how manic depressives have great difficulties with this kind of what we call a dialectic identity. They tend to establish an identity structure overidentify themselves with their respective social roles, with the spatiotemporal conditions of their everyday life, with their possessions, their dwelling, etc., being representatives of what we call object identities. Their overidentification is also shown by their hypernomic behavior that is a relationship to social norms without distance to social norms that would allow them to interpret the norms according to their respective situation. Thus, manic depressives tend to fulfill their duties in social roles in an excessive manner. They are also overidentified with their roles in

intimate partnerships in all these cases the object identities (the me in the sense of Mead) are normally counterbalanced by an ego identity better called a subject identity (the I in Mead's understanding), which allows for a certain distance to our object identities to react upon these by the subject identity. This is particularly important in the case of change or loss of one's object identities. Already in the premorbid state, the hypernomic behavior is characterized by a lack of ego achievements and consequently of lack of ego identity. This lack makes these patients particularly sensitive to situations such as retirement, chance of dwelling, any kind of role loss, which precipitate depression. The symptomatology of melancholic depression shows also this structure of overidentification. Because of the identity crises that result from a real, feared, or imagined loss of object identity, which cannot be compensated by a sufficient ego identity or subject identity, the patients cling to their object identities even more, which is expressed in the themes of their delusional ideas. According to the four fundamental kinds of basic dimensions of human identity, there are mostly four kinds of delusional topics to be found in melancholia: hypochondriacal delusion, corresponding to the identity we find in our lived body (Leib); delusion of impoverishment, corresponding to the identity we find in our possessions; delusion of guilt, corresponding to the identity we find in the evaluating judgments of others or of ourselves. Although the first three delusional themes relate to the clinging to or flight into object identities, delusion of insuffiency relates directly to the lack of ego identity of ego achievements.

In mania, compared to in depression, we find a precise inversion of the kind of being. Here, the patients struggle to overcome every kind of being determined by their object identities. In a willfulness to define themselves autonomously, they attend to assert their subject-I, negating their object identity. But these attempts fail because they cannot go without their object identities; melancholics are imprisoned in their overidentification with their object identities, but the manics feel themselves forced to use every opportunity to free themselves from every attachment to their object identities.

In the case of melancholia, the symptomatological–criteriological diagnostics would see a general inhibition and in mania a general loss of inhibition, whereas the phenomenological–anthropological diagnostics does not only point merely to the kind of behavior in these states, isolated from the person of the patient, but also to the respective change of his being, his change of identity, which secondarily results in the respective kind of behavior. Psychotherapy in these cases would also not only be oriented to the behavior but also to the identity of the patient in the sense of an identity therapy (Kraus, 1995). The particular value of a phenomenological–anthropological diagnostics is that the guidelines and norms of psychotherapy and rehabilitation result immediately from the diagnostic process itself, seeing a certain kind of identity structure as a particular existential type. Thus, the respective anthropological understanding of the illness has serious implications for the kind of therapy we prefer and has also consequences for the significance and special kind of rehabilitation.

Anthropology has promoted a series of therapeutic measures. We only mention Daseinsanalysis in the sense of Biswanger (1957, 1961), Blankenburg (1982), Boss (1951), Condrau (1963), Holzhey-Kunz (1994), Lang and Weiss (1992), and Lang (1992, 2011), existential psychoanalysis and existential psychotherapy in the wake of Sartre and other philosophers (Cannon, 1991; Hersch, 2003; Kraus, 1995; Mooji, 2012; Yalom, 1980), and the anthropological-integrative psychotherapy of Wyss (1992). Some of these authors and other psychotherapists (Kraus, 1995; Mundt, 1996; Schmitt, 2010) are eclectic in their psychotherapeutic measures but with an anthropological orientation.

Abstract

Informed consent is a philosophical and legal doctrine that has come to serve as the cornerstone of ethically sound clinical care in Western society. This doctrine requires that individuals truly understand and freely and knowledgeably make choices regarding their treatment. Informed consent is an ideal that emphasizes respect for the individual and places primacy on autonomous decision-making. Informed consent, furthermore, is inherently relational, that is, it occurs in the context of a professional relationship in which the fundamental values of the medical profession find expression. Fulfilling the ideal of informed consent in practice is an elusive aim, however. As suggested by intuition, clinical phenomenology, and empirical evidence, it is particularly challenging when consent is sought from individuals who suffer from mental illness. For this reason, it is important to consider the specific issues arising in informed consent in the context of mental health care. This article provides a clinically oriented overview of informed consent in mental illness by: (1) characterizing the core conceptual elements of informed consent; (2) applying informed consent concepts in mental health clinical practice; and (3) giving a brief overview of key empirical data related to mental and physical illness in clinical consent decisions.

Informed consent is a philosophical and legal doctrine that has come to serve as the cornerstone of ethically sound clinical care in Western society. This doctrine requires that individuals truly understand and freely make decisions regarding their treatment. Informed consent is an ideal that emphasizes respect for the individual and places primacy on autonomous decision-making. Furthermore, it is inherently relational, that is, it occurs in the context of a professional relationship in which the fundamental values of the medical profession find expression. Fulfilling the ideal of informed consent in practice is an elusive aim, however. As suggested by intuition, clinical phenomenology, and empirical evidence, it is particularly challenging when consent is sought from individuals who suffer from mental illness. For this reason, it is important to consider the specific issues arising in informed consent in the context of mental health care. This article provides a clinically oriented overview of informed consent in mental illness by: (1) characterizing the core conceptual elements of informed consent; (2) applying informed consent concepts in mental health clinical practice; and (3) giving a brief overview of key empirical data related to mental illness in clinical consent decisions.

Elements of Informed Consent

Informed consent does not occur in isolation or in a moment, nor is it reducible to a signature on a legal document. It is a shared, significant process between people – one of whom faces a series of evolving choices critical to his or her mental and physical health, the other of whom is a professional person entrusted with helping to define these choices astutely and present them truthfully, respectfully, and compassionately. In clinical care, promoting the health and alleviating the suffering of the individual patient will be the basis of any treatment considered in the consent process. Consent in this situation focuses on the patient's personal values, is based on the overall goals for care, and hinges on trust in the clinician–patient relationship.

Information

The sharing of appropriate information is the first of three core elements of informed consent. The patient should be provided with accurate and balanced information in understandable language. This information should include the anticipated risks and benefits of a given treatment, the procedures involved, and its alternatives and their expected outcomes. Alternatives may include implementation of another treatment or additional treatment, or it may involve no intervention upon the course of illness at all. While every minute detail cannot be reviewed in this discussion, rare but serious risks should be characterized in a manner that conveys their relevance and reality. Furthermore, the omission of information in the disclosure process should not be intended to deceive or mislead the person undertaking the decision.

Ideally information related to a matter requiring consent will be disclosed in a manner that fosters dialogue, allows for clarification of complex issues and the identification of misunderstandings, and keeps opportunities open for subsequent discussion as new issues emerge. In obtaining informed consent for treatment of mild depression, for instance, the clinician should discuss the variable course of depressive illnesses, including the potential for symptom resolution in the absence of treatment and the chance of recurrence without intervention. The clinician should review the rationale for a proposed antidepressant agent given the symptoms of the patient and the patient's attitudes and values. The discussion should cover the medication's known possible side effects, potential adverse effects, and their relative likelihood. The clinician should explicitly anticipate the choices that will be faced by the patient in the future in light of the therapeutic alternatives discussed and the nature of the illness. This discussion should be documented by the clinician as an important element of the care process.

Consent forms that accurately and completely describe a treatment and outline patient rights represent an important tool in the consent process. Consequently, consent forms should be developed carefully in terms of their understandability (e.g., simple but precise language), readability (e.g., size of font), content (e.g., purpose, risks and benefits, rights, responsibilities of the clinician/researcher), and related issues. Consent forms, furthermore, signify the importance of a new decision for the patient, and they give specific focus to the dialogue between the professional and the patient. Even general consent forms such as those for hospitalization or for initiating medication – which may or may not confer legal protection when a medico-legal conflict occurs – have this value. From a legal perspective, notes written by the clinician reflecting the disclosure dialogue with the patient may be far more salient and can carry greater weight.

Decisional Capacity

Decisional capacity, the second element of informed consent, represents a sophisticated clinical assessment of an individual's global and specific cognitive abilities within a particular context and in relation to a particular choice. It is distinct from 'competence' which is a legal determination, i.e., a formal assessment by a judge or other officer of the court regarding a person's ability to function within a general domain of one's life such as financial or medical decisions (Appelbaum and Gutheil, 1991). The presence of a serious symptom (e.g., delusions, memory loss, suicidal ideation, diminished cognitive functioning) or of a serious diagnosis (e.g., schizophrenia, dementia, major depression, developmental disability) does not mean that an individual lacks decisional capacity. Similarly, being a young adolescent or a very elderly person does not, *a priori*, preclude one from being decisionally capable. In the context of mental illness, decisional capacity assessment may be subtle, complex clinical work that entails constructing a cohesive sense of the individual's strengths and deficits in light of a number of factors. The type of decision to be made, the nature, time course, and severity of the person's symptoms, the patient's situation, and past experiences, personal values, psychological defenses or coping 'style,' and other factors should all be considered.

Decisional capacity itself has four principal components, each of which should be viewed on a continuum and not as 'all or none' phenomena (Appelbaum and Grisso, 1988). The first component is the individual's ability to express a preference (i.e., capacity for expression or communication). On the extreme end of the continuum will be severely ill psychiatric patients who are mute or catatonic, or who manifest complete language and thought disorganization, and therefore may be intermittently 'incapable' of communication. In the medical context, a patient who is comatose due to metabolic disturbances, aphasic secondary to a stroke, delirious, or unconscious after a head injury will also lack this most fundamental ability. There are times when this component of decisional capacity is very difficult to assess, such as in the spinal cord injured patient who communicates only through eye blinks, or the dysphoric person with Broca's aphasia who is frustrated by the process of generating words but has the capacity to understand and indicate choices. For these reasons, while the ability to communicate is often obvious, this assessment in many situations will require careful interactions with patients and astute observational and listening skills on the part of the clinician.

The second component of decisional capacity is the individual's ability to understand relevant information (i.e., capacity for comprehension). In talking with the clinician, the patient with this ability will be able to take in factual information regarding the nature of the illness, the need for intervention, the kinds of treatments under consideration, their relative risks and benefits, and the possible consequences of not intervening. Comprehension is influenced by intelligence, educational level, and prior experience. In assessing this dimension, it is critical that the patient state his or her understanding of the situation and the choices at hand in their own words. Otherwise it is difficult to know if the patient is using terms and phrases of the clinicians without truly knowing their meaning.

Third is the individual's ability to think through the decision in a way that is 'rational' and deliberate (i.e., capacity for reasoning or rational thinking). This component of decisional capacity relates to the person's analytical abilities given a specific set of facts or data and, like comprehension, is affected by intelligence and educational level. For instance, the 'rational' person, all other factors being equal, will consistently choose a medication that has a 75 % likelihood of treating the illness effectively over one that has a 50 % chance. Similarly, the 'rational' person will consistently choose a medication that poses fewer risks and promises fewer adverse side effects than another medication. In essence, this dimension of decisional capacity has to do with the ability to use objective information.

Fourth, and often most important, is the person's ability to make meaning of the decision and its consequences within the context of his or her personal history, values, emotions, and life situation (i.e., capacity for appreciation). Deeply dependent upon psychological insight, this is the most sophisticated component of decisional capacity. It can be very difficult to assess clinically. In some individuals with early dementia, for instance, a person's social graces and cognitive skills may be only superficially affected and yet these individuals may be unable to think through the meaning of an important treatment decision and its repercussions. In some patients suffering from either anxiety or affective disorders, the negative cognitive distortions inherent to their illnesses may interfere with their abilities to interpret information within a personal context, although other components of decisional capacity may be intact. Importantly, in people with severe mental illnesses such as schizophrenia, the simple presence of psychotic symptoms such as hallucinations or delusions may *not* interfere with the individual's overall decisional capacity, but the cognitive and insight deficits associated with the illness may interfere with their capacity for appreciation of the situation at hand. Alternatively, even the most gravely ill individuals may have difficulty expressing themselves and an incomplete sense of the factual information but may truly appreciate the severity of the situation and possess a deep and consistent sense of who they would like to make decisions for them.

Decisional capacity is therefore a rich construction, not simply reducible to an individual choosing a predetermined 'right answer' when making a decision of importance. It is the

person's ability to gather, assimilate, and use information, to truly see the reasons for and against a given option, and to develop a meaningful decision in the larger context of one's life. The seriousness and complexity of any specific decision will govern how rigorously these criteria are applied. In the context of serious mental illness, a person may be fully capable of deciding whether or not to begin a new psychotropic medication but, on a given day, may be incapable of deciding whether to enroll in a clinical protocol involving a medication-free interval and potential randomization to placebo. The standard for decisional capacity is also robust when a very ill patient refuses treatment that is highly recommended because of the benefit it is likely to bring to him (see discussion in the section Clinical Application of Informed Consent Concepts). This is not to say that patients cannot refuse treatment; when the risks of refusal are great, however, there is a greater responsibility on the caregiver to assure that the patient is genuinely capable of this decision and to manage its consequences.

Voluntarism

Beyond information disclosure and decisional capacity, the final element of informed consent is voluntarism or autonomy. Autonomy represents the expression of the authentic preferences of the individual in the absence of coercive pressures. Voluntary preferences may be tempered by the realities of the situation such as the presence of a serious diagnosis and the lack of 'curative' treatments for many mental illnesses, but should reflect the person's sustained and genuine wishes as evidenced in their expressed values and prior life decisions. Autonomous wishes may be deeply influenced by social and cultural expectations and psychological history. For instance, a patient who has been in the military may be oriented to hierarchical power relationships and may view a clinician's recommendation as an 'order' to be obeyed. Similarly, a seriously mentally ill person who has been institutionalized involuntarily in the past may see themselves as no longer possessing the right to their own choices. Illness processes may also affect patient preferences as well as the ability to express autonomous wishes. A person who suffers deeply either psychologically or physically may feel desperate and desolate, phenomena that can generate inherent internal coercive pressures. A person who has been the victim of violence may see themselves as relatively powerless. Finally, clinical syndromes that involve apathy, alexithymia, amotivation, or cognitive slowing may render ill individuals less able to identify and express their true wishes.

Clinical Application of Informed Consent Concepts

Translation of informed consent concepts to clinical practice is affected by the clinical status and situation of the patient. In emergencies, for instance, there may be little time for information sharing and mutual decision-making and the standard for consent is less rigorous than in other contexts. Acting beneficently, i.e., to save the life or preserve the health of the patient in an acute situation, is the clinician's duty in such circumstances. This is held to be critical ethically and justifiable legally; it is presumed that in such emergency situations the patient wishes to be helped and that the clinician has permission to act with the patient's well-being and best interests at heart. Often the patient, if alert and conscious, will explicitly assent to treatment in these circumstances, i.e., voluntarily accept the choice proffered by the clinician at the time. If the patient is unconscious or is unable to communicate at all, the clinician acts with the 'implied consent' of the patient.

When the patient refuses treatment in an emergent situation, however, a very rigorous standard for consent must be applied because of the likelihood of an adverse outcome and because there are many clinical factors that may be adversely affecting the judgment of the patient. Undiagnosed illness, delusional thinking, severe physical pain, emotional distress, and interpersonal pressure all may undermine the ability of the patient to make a fully informed, autonomous choice in an acute situation. Evaluation, hospitalization, and treatment, even against the apparent wishes of the patient, may be essential in such circumstances. Consider two illustrative patient cases:

Case Example 1

A man diagnosed with a serious mental illness characterized by psychotic and mood symptoms was brought to a psychiatric crisis unit after being found wandering on the street near his home. It was discovered that he had superglued his eyelids shut, and it was imperative that he receive medical attention immediately. He was outwardly calm, did not speak, answered questions through nodding, writing, and hand gestures, but actively refused to get into an ambulance to be taken to the medical emergency room. The clinician on duty that evening knew the patient well and was able to deduce that the patient's peculiar behavior was linked to a recurrent delusion he had when entering a manic period. In this case, the patient's ability to make a fully informed decision was impaired by his delusional belief that if he looked directly at people, they would be instantly destroyed by powerful lasers that had been implanted in his eyes. Once the clinician initiated a conversation about these beliefs with the patient, it was possible to clarify that the patient wanted help and that he was willing to accept treatment, but was terrified that he would hurt people or himself be killed. The patient thus had some decisional ability and could offer assent for emergency care. The clinical team opted to pursue a legal process that would allow involvement of a time-limited treatment guardian due to concerns over the patient's compromised insight and judgment and the severity of his delusions.

Case Example 2

An agitated man demanded discharge from a surgical unit two days after an emergency appendectomy. He had elevated heart rate, blood pressure, and temperature, had signs of abdominal infection, and yet was insistent that he leave the hospital. The medical team was conflicted about granting the patient an 'AMA discharge' ('Against Medical Advice') – the nurses and residents believed this to be the patient's 'right to refuse treatment' but the attending clinician did not agree. On initial psychiatric evaluation, the patient showed irritability and very

subtle indications of diminished attention, was oriented except to day of the week, and had no other apparent abnormalities on an abbreviated mental status examination. He was noted to be tremulous. He was placed on involuntary 'hold' status. Within an hour, the patient was agitated, disoriented, and expressed disorganized thoughts. Additional history was then obtained that the patient drank one to two pints of vodka daily prior to admission. Postsurgical infection in combination with alcohol withdrawal had triggered a significant delirium, an early indication of which, ironically, was his treatment refusal and discharge demand. His most distressing symptoms and disorientation resolved rapidly with treatment, and he withdrew his request to leave the hospital.

When a patient refuses treatment there may be a significant clinical issue that requires close attention, and involuntary treatment may be imperative. Clarification of underlying clinical considerations in such circumstances is the caregiver's primary responsibility – a duty grounded in the bioethics principles of respect for persons, clinical standards of care, fidelity, and beneficence. Careful evaluation of the patient's true strengths and abilities is important so that he or she may exercise choice in every area possible. The intent is not to undermine the patient's autonomy. Rather, it is to empower the clinician only insofar as to help advance the health and well-being of the patient and to assure that the patient is optimally able to express his or her true wishes to accept or decline a given therapeutic approach. In sum, in situations where clinical decisions may have very serious or irreversible health consequences, including death, informed refusal of treatment must fulfill the most stringent standards.

The goal of informed, voluntary decision-making may be more clearly fulfilled in the context of care for chronic illness. Over the course of time, the clinician may come to know the patient – their symptoms, their values and concerns, their responsiveness to treatment interventions, and their personal supports. In turn, the patient may have a greater sense of trust, express themselves with greater openness, and gather more complete information about the illness and potential therapeutic interventions. The patient with a chronic illness also lives out the consequences of side effects, adverse reactions, and benefits of treatments in a manner different from the patient with a time-limited health problem. In this context, the patient may better appreciate how their illness and treatment affect other aspects of their life, and it is possible to come to know their preferences and concerns with greater certainty. Expressing autonomous wishes and deciding upon specific treatment approaches and the overall goals of therapy through mutual understanding and dialogue are more intrinsically possible in the context of chronic illness. The standard for consent in chronic illness, thus, is very rigorous in terms of the patient's level of information, opportunities to enhance decision-making, and creating a circumstance in which patients may indicate their wishes and hopes.

In clinical practice, psychiatric advance directives may be valuable in translating concepts of informed consent to patient care decisions. Advance directives articulate patient preferences for future care. Advance directives are often formal written papers created and signed by the patient; they may also consist of a body of documentation developed by the patient, family members, and clinicians regarding his or her wishes and values concerning personal health care. Advance directives are helpful in that they serve as a reference for the clinician if the patient becomes decisionally incapable or compromised. For example, knowing that they had a pattern of developing compromised judgment during periods of mania, a patient with bipolar disorder completed an advance directive requesting that treatment be instituted despite their (anticipated) protests. Advance directives also provide evidence of the patient's past personal healthcare preferences that may result in controversial clinical decisions, e.g., when patients refuse treatment based on deeply and consistently held personal convictions such as the refusal of blood transfusions by a patient who is a Jehovah's witness. Ideally, these issues will not be addressed for the first time in a moment of great crisis. They should be anticipated, discussed, and documented carefully beforehand. Advance directives do not, under any circumstances, replace the wishes expressed by a patient who is currently decisionally capable. Moreover, there should be opportunities to adapt, or even reverse, earlier decisions as one cannot always tell prospectively how one will respond in a crisis situation. For these reasons, advance directives may guide but can never supplant prudent, reflective clinical decision-making.

In surrogate decision-making, healthcare choices are made for the decisionally impaired patient by another person. This person may be a spouse, sibling, adult child, friend, or a court-appointed guardian. The surrogate decision-maker has the responsibility of serving the best interests and well-being of the patient while seeking to make decisions that are faithful to the personal values and prior wishes of the patient. This can be difficult. In some situations, the patient's wishes are not known. In other situations, the patient is too young or too cognitively compromised to have demonstrated their personal values. In yet other situations, these values and wishes are known and appear to conflict with accepted standards of clinical care. Consequently, in working with surrogate decision-makers, it is important for clinicians to clarify the goals and value system governing the choices made on behalf of the patient. It is also crucial that the patient's decisional capacity be assessed accurately and, in most circumstances, the patient's symptoms be treated aggressively so that they can contribute to the choices made to whatever extent possible.

Empirical Studies on Consent in Clinical Care

Nearly 400 studies performed since 1970 suggest that informed consent is an ideal that is often difficult to achieve in clinical and research practice involving people with physical and mental illness (Sugarman et al., 1999). These data indicate, however, that issues faced in clinical care for mental illness are not radically different in degree or kind from those encountered in the treatment of physical illness (Stanley et al., 1988). Moreover, an extensive body of evidence on consent consistently demonstrates the poor readability, understandability, and ineffectiveness of formal consent documents in clinical care (Grossman et al., 1994). An important recent advance in the informed consent field has been the development of the MacArthur Competence Assessment Tool for Treatment (MacCAT-T) (Grisso et al., 1997). This is a structured interview designed to assess patients' clinical care decision-making

abilities based on empirical work conducted over 10 years by Appelbaum and N Grisso. While this instrument is best utilized as a tool for approaching decisional capacity evaluation, not as a definitive 'test' of competence, it will introduce greater consistency of consent standards to both scientific and clinical arenas.

Evidence on consent in the care of mental illness reveals many key challenges for clinicians (Roth et al., 1982). Studies of psychotic, affective, and dementia disorders, for instance, have shown that symptoms of mental illness may adversely impact information-based or more strictly cognitive aspects of consent (Roberts, 1998). In the 1995 MacArthur Treatment Competence Study (Appelbaum and Grisso, 1995), the decisional abilities of patients with schizophrenia or major depression, patients with ischemic heart disease, and non-patient community volunteers (total n=498) were assessed. When acutely ill, the psychiatric patients in this study had greater difficulties with decision-making on several formal cognitive measures than did the medically ill patients and community participants. The problems were more severe for individuals with psychotic symptoms than for depressed individuals. Clinical treatment led to significant improvement of these deficits, resulting in closer resemblance across the three groups.

Smaller studies echo these findings. An early study by Schachter et al. (1994) involving 38 schizophrenia patients revealed that the presence of conceptual disorganization, delusions, and hallucinations was associated with patients' poor performance on the information elements of consent. Appelbaum et al. (1981) assessed 50 people admitted to a mental health inpatient unit and found that most were unable to consent to hospitalization. Later this team evaluated 100 voluntarily hospitalized psychiatric patients, finding that a significant minority did not understand information presented to them on the purpose of hospitalization and discharge (Appelbaum et al., 1998). Beck (1988) evaluated the capacities of 56 psychiatric patients on antipsychotic medications, revealing that they had limited understanding and appreciation of their treatment. Stanley et al. (1988) compared the reasoning ability of elderly individuals suffering from major depression (n=45) and dementia (n=38) with elderly control subjects (n=20). The cognitively impaired dementia patients and, to a lesser extent, the depressed patients had significant deficits on a number of decision-making items. Similarly, Marson et al. (1995) used a clinical vignette-based instrument to measure the level of competence exhibited in medical treatment decisions by individuals with dementia and healthy comparison subjects. Not unexpectedly, this work revealed that the severity of cognitive impairment in dementia correlated with lack of ability to formulate logical reasons for treatment choice, i.e., addressing the 'rational reasons' dimension of decisional capacity. Interestingly, global measures of dementia severity such as the Mini-Mental Status Exam were not predictive of clinical decision-making capacity.

Studies of advance directives and surrogate decision-making also have important implications for mental health care. Several survey and interview studies have revealed that advance directives are underutilized (Bradley et al., 1998) and that patient preferences are rarely identified prospectively (Seckler et al., 1991). In terms of surrogate decision-making, several studies have shown that most elderly patients would prefer that a family member such as a spouse or adult child serve as an alternative decision-maker (High, 1989). Studies of hypothetical decision-making by proxies suggest that they may not assess patients' wishes accurately, however Sachs et al. (1994) studied 42 decisionally capable dementia patients, 64 proxy decision-makers, and 60 well elderly individuals and found that the decision-makers' predictions of patient preferences were overall discordant with the patients' own stated wishes. Similarly, Warren et al. (1986) studied participation choices made by proxy decision-makers and 168 decisionally capable nursing home patients with respect to hypothetical, minimal risk research projects. The results demonstrated that the surrogate decision-makers used criteria other than the patient's predicted preferences in making these choices.

Clear evidence is also emerging that the barriers to consent may be amenable to intervention, offering significant hope (Roberts et al., 2000). Interventions in which information is presented verbally and in writing, using clear and understandable language, have been shown to improve patients' understanding of consent decisions (Carpenter et al., 2000). The timing of consent information and the provision of information in a relaxed manner or on repeated occasions is important to patients' abilities to integrate and apply this data (Roberts, 1998). Treatment of symptoms, ranging from hallucinations to physical pain, has been observed to improve the quality of patients' decision-making. Finally, clinician behaviors that reflect how the consent process is valued, e.g., by giving time to the consent dialogue, have been found to be valued by patients and surrogate decision-makers (Roberts and Roberts, 1999). The observation that educational efforts, symptom treatment, and attitudinal obstacles can be addressed suggests a number of constructive approaches to consent in the context of clinical care for the mentally ill.

Abstract

Sigmund Freud's biography, the development and interpretation of psychoanalysis constitute an important chapter in twentieth-century cultural and intellectual history both as a body of theory and as cultural practice. An ongoing attempt to determine the meaning of Freud and psychoanalysis has led to the publication of hundreds of volumes, and the historiography of psychoanalysis has found its own place within the history of science. Historical literature about psychoanalysis ranges from the self-representations and autobiographical works of Freud to the first official biography, from moderate revisionism and contextualized approaches to the harsh, and at times hostile, clinical, feminist, epistemological, hermeneutical, and psychobiographical critiques. A general history of psychoanalysis as a single science can be cataloged in three ways: (1) as a history of the psychoanalytic theories from Freud to the present; (2) as a history of the psychoanalytic movement, its institutions and practices; and (3) as a self-reflection on the historiography of psychoanalysis itself.

Sigmund Freud's biography, the development and interpretation of psychoanalysis constitute an important chapter in twentieth-century cultural and intellectual history both as a body of theory and as cultural practice. Each culture and time has absorbed Sigmund Freud (1856–1939) and psychoanalysis differently. A general history of psychoanalysis can be cataloged in three ways: (1) as a history of the psychoanalytic theories from Freud to the present; (2) as a history of the psychoanalytic movement, its institutions and practices; and (3) as a self-reflection on the historiography of psychoanalysis itself.

A History of the Psychoanalytic Theories from Freud to the Present

The development of Freud's theory of the unconscious and his psychotherapeutic method can be understood on the basis of his professional development in the context of a process of differentiation and specialization, in particular, medicine and philosophy, in the late nineteenth century. Historical works of the kind, for example, studies of the scientific and social context and the institutional structure of the field, have created a methodologically sophisticated and broad view of psychoanalysis. Various types of hermeneutical studies of psychoanalysis itself, that is, visions of it as a system of symbols and as a method for culture-decoding rather than as a type of natural science, have broadened the view of the history of psychoanalysis. Jean Laplanche and Jean-Bertrand Pontalis's *Vocabulaire de la Psychanalyse* (1967), the first conceptual dictionary of psychoanalysis, is based on the techniques of the history of philosophy and the French tradition of the epistemology of the sciences. As the basic concepts of the psychoanalytic theory have undergone changes that reflect the development of the sociopolitical climate, the authors have incorporated the later concepts of Freud and his followers as well as critics who created new theories and schools of psychoanalysis (e.g., Melanie Klein, Jacques Lacan). Their attempts have stimulated a whole universe of separate hermeneutical and epistemological studies, and especially, with the centenary of the birth of psychoanalysis various encyclopedic works and summaries have been published (e.g., Erwin, 2002; Skelton, 2006).

Freud's psychoanalysis with its concepts *subjectivity* and the *scientific empirical method* has been interpreted as a characteristic product of Viennese modernity, and has been seen as a parallel to phenomena like Zionism and Austromarxism. Bourgeois society and European modernity experienced significant crises in Vienna of the *fin de siècle*, where psychoanalysis was founded in the last decades of the Austro-Hungarian Monarchy. During the period between 1890 and 1910, extraordinary achievements were made in the areas of music, literature, art, and science. These were fundamentally influential for new developments in observation and thought in the twentieth century, and the psychoanalytic theory enjoyed its heyday in the years before World War I. The following factors were generative forces behind the *fin de siècle* creativity: the rise of new cultural founding figures of the liberal bourgeoisie, the influence of the Jewish intelligentsia, and the upward mobility of immigrants from the Austro-Hungarian Empire; the resistance against the political control, bureaucracy and the repression of the Roman Catholic Church and censorship; the cultural networks established with European centers and circles abroad; the import of foreign ideas; and the intellectual exchange between the submetropoles of the countries of the monarchy (Nautz and Vahrenkamp, 1993).

From 1859 until 1938, Sigmund Freud lived and worked in Vienna, and the significance of Vienna as the site of psychoanalysis' foundation and development is evident. Socio-politico-cultural studies have dealt with Freud's *fin de siècle* (see Schorske, 1981; McGrath, 1986), viewing psychoanalysis within Viennese culture, for example, at the juncture of a specific time and place. Special interest has focused on Freud's Jewish identity and the relationship between Judaism and psychoanalytic theory. Psychoanalytic theory and Freud's biography were and in many ways still are intertwined in a unique way. Therefore, the historian is in the position of having to treat psychoanalytic concepts as both strictly personal documents and as documents connected to a broader theoretical system. In Freud's early texts, the evolution of psychoanalytic theory is presented linearly, as though it was fundamentally the same as any other scientific field, but there are serious historiographical difficulties entailed in approaching psychoanalysis in this fashion. Freud's self-analysis, his

autobiographical writings, and self-created image of psychoanalysis as a science and various theoretical concepts of psychoanalysis (e.g., seduction theory, dream interpretation, Oedipal conflict, resistance, repression, transference, and countertransference) have become prominent in the field of psychoanalytic historiography, including Freud's own changes of theory throughout his life, as well as post-Freudian developments (e.g., drive-psychology, ego-psychology, object-relations theory, attachment theory, the development from defense to adaptation, from instinctual to motivational diversity, the development of the neurosciences).

A History of Freud's Biography, the Psychoanalytic Movement, and Its Institutions and Practices

In the historiography of psychoanalysis, the genre of Freud studies has been differentiated from the historical examination of the psychoanalytic movement in its local national centers e.g., Berlin, London, or Paris and within special cultures e.g., Japan or India. Biographical studies dominate over sociohistorical works, and the focus has been for a long time on the struggle over legacy and legitimacy rather than on a social history of the field.

Freud Biographies

Three groups of historical literature about Freud have been described by historians: (1) publications of primary sources, for example, Freud's correspondences; (2) publications of historical materials concerning case studies and theoretical works of Freud; and (3) critical-academic studies about psychoanalysis. The history of Freud biography and the psychoanalytic movement began with Freud's autobiographical works *On the History of the Psychoanalytic Movement* (1914) and *An Autobiographical Study* (1925), and in his own historical papers, Freud – in his one-sided but coherent story – suggests that the history of psychoanalysis is basically the history of refusals, resistances, and the regroupings of the orthodox Freudian ideas, institutions and people. History of psychoanalysis also appears at times to be synonymous with the history of splits, schisms, and dissidents. But, just as the proliferation of schools and the consequent battles among and splittings within psychoanalytic institutes stimulated abundant polemics, these upheavals also stimulated reworkings of almost every important item in the history of Freud biography.

Dreams from *The Interpretation of Dreams*, patients from *The Studies on Hysteria* and later case studies have been analyzed and reanalyzed by scholars from new perspectives; all the schisms and quarrels in the history of psychoanalysis were rediagnosed by the latter-day schismatics and schism-haters. Based on newly accessed archival material and historical information, early speculations and widely differing interpretations have been reconsidered. Freud biographies have addressed almost every aspect of Freud's life (profession, social status, political views, culture, religion, affection-emotion), sometimes in a general fashion, sometimes in a very specific manner, and reflecting the time and the standpoint of their authors. To forestall future falsifications in popular biographies and early attempts at studying Freud's biography by his pupils and followers, Freud's youngest daughter Anna Freud, a psychoanalyst herself, felt prompted to authorize Ernest Jones to write a first full-scale biography (Young-Bruehl, 1998). Freud studies properly began with the pioneering research of Siegfried Bernfeld; his scholarship was invaluable to Ernest Jones when putting together his trilogy *The Life and Work of Sigmund Freud* (1953–1957). As a member of the first generation of loyal followers, Jones' monumental work became the precipitant for a third type of historical accounts: critiques of Jones's biography, or what might be called second-order biographies.

For a long time, Freud's prominence nurtured the illusion of an isolated progression of psychoanalysis apart from sociopolitical developments as well as medicoscientific trends at the time. A cultural–historical approach to Freud became more intense as the 1960s unfolded. With Henri Ellenberger's *The Discovery of the Unconscious* (1970), a mode of Freud biography contextualizing Freud began to flourish, taking the precursors of Freud's ideas more into account than Jones did.

The Psychoanalytic Movement

Interest in supporters, students, and contributors of Freud has long been marginal or limited to only the most well-known representatives. With the publication of *The Minutes of the Vienna Psychoanalytic Society* (Nunberg and Federn, 1962–1975), a new focus was put on the institutional framework, the form in which these scientists cooperated, and how they organized their professional and personal exchanges. Works on Freud's friendships and professional relationships include the dynamical and sociological aspects of the formation of groups, the production of scientific knowledge, the structure of mastery and slavery (often basic to the formation of psychoanalytic institutions), as well as more contextually embedded accounts of specific psychoanalytic cultures. Further, *Freud and his Followers* (Roazen, 1975) stimulated studies of the family networks and subnetworks; as a consequence, biographies of early pupils and later analysts have emerged. Their adherent or schismatic relations to Freud figured largely in these accounts. A special body of historical literature has focused on the role and influence of female patients and analysts. The founding of new psychoanalytic schools has created a new intellectual–historical approach, including the professionalization and institutionalization of the discipline in different cultures and at different times. From the early days of psychoanalysis, the internationalization of psychoanalysis had its own motor and effect on theory and practice (e.g., Kutter, 1992, 1995; Makari, 2008). Taking geographical and temporal particularities into account, a Western (European and North American) perspective has been criticized.

Economic and political circumstances, as well as cultural and sociohistorical connections, have all influenced the theoretical, practical, and organizational developments of psychoanalysis as a discipline and are part of the production of psychoanalysis as a corpus of knowledge. Fenichel (1998) has observed the impacts of social and political reality on the production of psychoanalytic theory and practice during the years when Central European Jewish psychoanalysts, candidates in training and their families were forced to flee National Socialist Germany and Austria and the occupied

countries in Europe. The production of scientific findings and the transformation and transfer of knowledge as social processes in which internal and external factors are in a constant exchange does not minimize the role of the founder of the science of the unconscious in its beginning, but it destroys the illusion of a single isolated discovery. The shifts in the history of psychoanalysis can be seen and interpreted as a complex, dialogical, multiauthor enterprise and depend on the studies of the special scientific tradition and the study of psychoanalytic microcultures (see Hale, 1995; Lockot, 1985; Roudinesco, 1982–1986).

A Self-Reflection on the Historiography of Psychoanalysis itself, and the Problems of Methodology

The history of psychoanalysis has been a rapidly growing, controversy-ridden, and attention-attracting area. Over the past 40 years, each of the historical visions has inspired and/or provoked a revision, and each revision a counterrevision. The history of psychoanalysis has to take into account the peculiar, complex, and powerful interplay among psychoanalysis, historiography, and ideology; because this has not been recognized, many widely disparate accounts of psychoanalytic history have been proffered. Neighboring fields, such as the history of medicine, neuroscience, philosophy, psychology and science, women's studies, the history of law, crime and deviance, the history of professions, the history of sexuality, the history of the body, and cultural studies, literature, queer/gay/gender studies, have had their impacts on the historiography of psychoanalysis as well.

Studies in the area of Freud biography and the pre- and early history of psychoanalysis have received more attention. Because connections with later periods seem less powerful and convincing, the fixation on Freud himself and, even more particularly, on the first decades of Freud's discoveries have meant that later developments during and especially since Freud's lifetime are achieving less attention.

The various schools of psychoanalysis have fashioned for themselves idealized genealogies, lines of intellectual filiation between great minds of the past and contemporary practitioners, tracing a suitable line of evolution, and have been selective of their usable past. They may also assist in sharpening contested interdisciplinary or intradisciplinary boundaries in which 'positive' episodes are memoralized, taken as characteristic of the essence, while 'negative' ones are omitted, serving to legitimate particular theories and methodologies and delegitimizing others. Today, scholars have come to the opinion that historical accounts of psychoanalytic theory and practice should include thoughts and speculations about the special acquisition and transmission of psychoanalytic knowledge.

A 'coherent' picture of Freud and the psychoanalytic movement has undergone a profound change. In the historiography of psychoanalysis, at least two different schools of thought have been described: the 'official' history of Freud, which has been largely though not exclusively produced and consumed by practicing psychoanalysts, and a 'revisionist' approach that has emerged in the last decades and has been mainly produced by people working outside of institutional psychoanalysis (e.g., historians, psychologists, philosophers, sociologists, political scientists). For a long time, the two groups have debated separately – with a trend to specialization and fragmentation thereby repeating the fragmentation of the object they are analyzing – and have tried to avoid other findings. But lately, a dialogue between historians and clinicians – both interested in history – concerning the history has arisen, and there have been attempts to overcome prejudices. One outcome of this dialogue has been the formation of local and international organizations and discussion groups and the establishment of special journals and periodicals as well as various new platforms on the Internet. Still, the issues of language, including the problems of translation and the questions concerning authorship and audience remain central, as in other scientific disciplines. Language questions have been correlated with speculative histories on Freud and the psychoanalytic movement.

After the height of the professional prestige of psychoanalysis, when there was remarkably little criticism from historians of psychiatry, a revisionist historiography of psychoanalysis was stimulated by e.g., historians, sociologists, philosophers, literary scholars, feminist authors, cultural scientists, and public intellectuals; traditional biography and the general longitudinal narrative were followed by the study of institutions introducing the ideal of objective, systematic, and quantitative analysis, having in mind methodologically sophisticated, empirically substantial, and sociologically oriented scholarship. On the other hand, as scholars have argued, the demystifications of hagiographical idealizations have often only generated 'heroic' neo-Marxist and Foucauldian remystifications. Revisionist and hagiographical literature have been diagnosed by contemporary scholars as both reductionistic and lacking self-reflection.

Psychoanalysis as a theory and a profession emphasizes the value and virtue of self-awareness and in its therapeutical practices asks for an introspective mode of inquiry nevertheless, with a few exceptions, it has remained resolutely unintrospective about the methodological and ideological conditions under which it writes the narrative of its own past. That is all the more peculiar in light of the past decade's extensive and sophisticated discussion concerning different conceptual, methodological, and epistemological strategies for writing the history of science generally. Two approaches have been observed, the internalist approach, stressing cognitive development, and the externalist approach, focusing on the social, economic, political, and professional determinants of scientific theory and practice. All history writing has been diagnosed perspectively as the expression of a particular historical environment, culture, background, and self-consciousness among cultural-critics. LaCapra (1988) emphasizes the Freudian point that any historian's relationship with the past, and through that with the present, is a transference relationship, and that, in this transference, repetition and denial come more easily than working through and mourning (Smith and Morris, 1992; Young-Bruehl and Schwartz, 2011)

Jones' idealization of Freud has been rejected, and, particularly in the medium of psychobiography, a much more contextualized, conflicted, and complicated founder of psychoanalysis has emerged in the historical literature. Jones

did not interpret blanks in his documentation as secrets of resistances, but nowadays psychologically informed biographers consider the fact that many of the most important things in people's lives are never recorded.

Contrary to the sophisticated histories of Freud's unfolding discoveries, historians have lamented the difficulties of psychobiography, and some of the key methodological problems concerning childhood experiences, the workings of the mind, and the character of thought, have been widely recognized – although such recognition has not yet informed a major historiographical work on psychoanalytic biography and history writing.

Despite the progressive de-Freudianization of psychiatry and psychology in general, Freud's place as one of the supreme minds of the twentieth century remains secure for most historians. Psychoanalysts have altered psychoanalytic theory over the course of time, their theoretical and methodological findings depending on their analysands, their social context, and the historicopolitical changes in general. Historiography has altered accordingly, considering and tolerating the complexity instead of simplistic and popular versions of psychoanalysis.

Psychoanalysis in Sociology

Abstract

In what follows the appropriation of psychoanalysis in sociological theory is charted, with four key sociological traditions considered: first, several early and influential articulations of psychoanalysis and sociology developed in Europe (particularly as represented in the work of the Frankfurt school of sociology) and North America (especially in the writings of Talcott Parsons); second, structuralist and poststructuralist appropriations of psychoanalysis as refracted in sociological debate; third, feminist and postmodern social theory; and finally, more contemporary developments within European psychoanalytic traditions that have influenced the social sciences and humanities.

This article addresses the complex, and often ambivalent, relationship that psychoanalysis has had with sociology. The psychoanalytic tradition, beginning with Freud, is critically examined, primarily in terms of the impact of Freud's theory of the unconscious for theorizing both individual and social structural aspects of the contemporary epoch in sociological research. The appropriation of psychoanalysis in sociological theory is then charted, with four key sociological traditions considered: first, several early and influential articulations of psychoanalysis and sociology developed in Europe (particularly as represented in the work of the Frankfurt school of sociology) and North America (especially in the writings of Talcott Parsons); second, structuralist and poststructuralist appropriations of psychoanalysis as refracted in sociological debate; third, feminist and postmodern social theory; and finally, more contemporary developments within European psychoanalytic traditions that have influenced the social sciences and humanities.

Psychoanalysis, as developed by Sigmund Freud and his followers, has had a major impact upon sociological theory and modern sociology. Freud's central discoveries – the unconscious, sexual repression, the Oedipus complex, and the like have been deployed by sociologists to interpret and discuss the self and human subjectivity, gender and sexuality, the family and socialization, language and ideology, as well as the formation of cultural identities and forms of political domination. Notwithstanding this impact, sociology as a discipline has long had a difficult, and indeed fraught, relationship with psychoanalysis. Sociologists have criticized psychoanalytical theory on the grounds of its methodology, epistemology, and ontology. Despite these criticisms, many contemporary sociologists remain engaged with, and some strongly committed to, the psychoanalytic tradition in order to conceptualize the relation between the individual and society, especially the complex, contradictory ways that human subjects acquire and reshape the ideas, values, symbols, beliefs, and emotional dispositions of the wider society. This has been particularly evident over recent decades, in which Freudian themes and psychoanalytic motifs have been used to analyze sexual politics, issues of identity and lifestyle, as well as the debate over modernity and postmodernism.

Freud and the Sociological Imagination

Freudian psychoanalysis shares with sociology a primary preoccupation with the fate of the individual or self in the context of social relationships and the wider cultural process. While Freud's own writings were primarily derived from his clinical work with patients, and to that degree are at variance with the core methodologies of mainstream social science, his characterization of human personality and self-identity has clear parallels with, say, Thomas Hobbes' theory of human nature or Karl Marx's account of the self-seeking individual in organized capitalist society. Yet whereas both Hobbes and Marx stress the impact of social forms in the constitution of the self, Freud's methodological starting point is the individual psyche, principally the instinctual impulses and libidinal longings that shape the human imagination. The self for Freud is radically fractured or divided, split between consciousness of identity and the repressed unconscious. The biographical trajectory of the self, according to Freud, is carried on against the backdrop of this radical otherness of the unconscious, a domain of the psyche that infuses three agencies of the psyche: id, ego, and superego. The id, lying at the root of unconscious desire, is that which cannot be symbolized yet constantly strives for expression in our daily lives, manifesting itself in dreams, daydreams, slips of the tongue, and the like. It is a hidden area of the self, which knows no reality, logic, or contradiction; the unconscious is at the root, says Freud, of how people, for example, can simultaneously love and hate their parents. The superego, as internal anchoring of cultural prohibition, is founded in this id. Desire, according to Freud, infiltrates all human intentions, ideals, and imperatives. Similarly, Freud sees parts of the ego as interwoven with the force of the id, the self arising as a product of the unconscious. While Freud's writings on human personality and the constitution of the self have proven of interest to sociologists, it is his account of the relations between self and society – primarily his late writings on civilization – that has most influenced the development of modern sociology. In his late writings, Freud comes to see human beings living under the destructive force of a terrifying death drive, as well as strict cultural prohibitions on sexual desire and enjoyment. These themes are set out in his

magisterial books *Beyond the Pleasure Principle* (1920) and *Civilization and its Discontents* (1930). Civilization, writes Freud, is repressive. Society imposes severe psychic demands upon individuals to achieve cultural conformity, demands that produce intense personal misery and neurotic suffering. Some sociologists have interpreted this aspect of Freud's sociology as at one with the conservative social thought of Hobbes, likening it to the theorem that cultural reproduction demands the overcoming of chaotic passion. But it is clear that this involves a radical misunderstanding of Freud's position. The dualisms that Freud uses to analyze modern civilization (consciousness/unconscious, desire/repression, the pleasure principle/the reality principle, Eros/Thanatos) suggest a disjunction between self and world. According to Freud, ambivalence is at the core of the individual's relation to the self, to others, and to society.

Freud's writings on the fate of the self in contemporary culture have strongly influenced sociological debates – from Herbert Marcuse to Michel Foucault. Too much repression, Freud says, leads to intense unconscious anguish, hostility, and rage. At such a point, the intensification of unconscious desire can release the 'mental dams' of sexual repression in a far-reaching way. The issue of the subjective seeds of social and political transformation are thus at the heart of Freud's theoretical contribution to sociology and social theory.

The Integration of Psychoanalysis and Sociology

With regard to social analysis and sociological theory, Freudian ideas have loomed large in the sociological conceptualization of human subjectivity and interpersonal relationships, sexuality and modern culture, as well as the mix of reason and irrationality in politics and history. There have been three key sociological developments in this connection: first, there has been several early and influential articulations of psychoanalysis and sociology developed in Europe (particularly as represented in the work of the Frankfurt school of sociology) and North America (especially in the writings of Talcott Parsons); second, structuralist and poststructuralist appropriations of psychoanalysis as refracted in sociological debate; and finally, feminist and postmodern social theory has been significantly shaped by psychoanalysis.

Early Disciplinary Articulations

In Europe, Herbert Marcuse and Theodor Adorno – leading members of the Frankfurt school of critical theory – turned to Freud in order to reconceptualize the relation between self and society. The political motivation prompting this turn to Freud had its roots in Marcuse's and Adorno's attempts to conceptualize the rise of fascism, Nazism, and also the spread of bureaucratic capitalism. From Freud's theory of the Oedipus complex, and particularly his theorem concerning the repression of infantile sexuality, Marcuse and Adorno developed the notion of 'the authoritarian personality'. Driven by a desire for conformity and clear rules, the authoritarian personality was viewed by Marcuse and Adorno as a character type strongly prevalent in the German middle classes, a character type who hungered for strong leadership, social order, and regulation. Not only in Nazi Germany, however, was this personality type to be found; in the advanced liberal societies of the West, tendencies toward authoritarianism and conformism are increasingly evident. Marcuse thus spoke of the emergence of 'one-dimensional man'.

Marcuse's radical Freudianism, in particular, won a wide audience in the 1960s – not only in social science circles, but among student activists and sexual liberationists. Arguing that the so-called sexual revolution of the 1960s did not seriously threaten power structures of the established social order, Marcuse sought to show how demands for freedom were routinely rechanneled for commercial interests. The core of his analysis rested upon the distinction he drew between basic and surplus repression. Basic repression he defined as the minimum level of psychological renunciation demanded by the social structure and cultural order. Repression that is surplus, by contrast, refers to the intensification of self-restraint demanded by asymmetrical relations of power. Marcuse describes the 'monogamic-patriarchal' family, for example, as a site of surplus repression. Interestingly, while Marcuse saw signs of surplus repression increasingly everywhere in late capitalist society, he remained remarkably optimistic about the possibilities for social and cultural change.

On the other side of the Atlantic, a different approach to the integration of psychoanalysis and sociology was fashioned. The core thematic of this approach concerned social order, socialization, and the reproduction of the social system. The grand theorist of American sociology, Talcott Parsons, employed Freudian ideas to understand how basic symbols and values are internalized by human subjects throughout the socialization process. According to Parsons's appropriation of Freud for social theory, the structure of human personality is an outcome of an internalization of desired objects, role relationships, and ethico-cultural values that make up the broader social network. In this approach, it is the linkage of personality structure, the social system, and the cultural system that is stressed. Unlike Marcuse's and Adorno's emphasis on the social manipulation of the unconscious, Parsons finds a kind of preestablished harmony between the individual and society.

Structuralist and Poststructuralist Psychoanalytic Sociology

For many years, the integration of psychoanalysis and social analysis developed by the Frankfurt school was commonly regarded as the most sophisticated and important work in this subfield of modern sociology. From the late 1960s onward, however, the impact of French theory, particularly structuralist and poststructuralist philosophy, became increasingly influential in terms of theorizing the social dimensions of psychoanalysis. The key figure in this connection was Freud's French interpreter, Jacques Lacan. Seeking to rework the core concepts of psychoanalysis in the light of modern linguistics, Lacan argued that the unconscious exemplifies key features of language; as Lacan famously argues, "the unconscious is structured like a language". The subject or 'I', according to Lacan, is not self-transparent, but is rather located in a system of signification from which identity is fashioned. For Lacan, intersubjectivity is at the center of psychological functioning and its disturbances; distortions or pathologies at the level of the self are, says Lacan, located in 'the discourse of the other'.

It is perhaps Lacan's essay "The mirror stage as formative of the function of the I" (1949) that has come to exert most influence on contemporary sociological theory. In the essay, Lacan conceptualizes the small infant's initial recognition of itself in a mirror or reflecting surface, and of how this generates a sense of identity. Through the mirror, says Lacan, the infant makes an imaginary identification with its reflected image, an identification that the infant reacts to with a sense of jubilation and exhilaration. But the mirror image of the self for Lacan is, in fact, a distortion; the mirror lies. The mirror stage is radically 'imaginary', in Lacan's theorization, since the consolingly unified image of selfhood that it generates is diametrically opposed to the bodily fragmentation and lack of coordination of the child. These imaginary traps and distortions are a universal and timeless feature of self-organization, and Lacan sees such illusions as directly feeding into and shaping pathologies of the self in contemporary culture.

Lacan was not especially interested in the social applications of psychoanalysis; it was one of his followers, the French Marxist political philosopher Louis Althusser, who brought Lacanian theory into the center of key debates in sociology. In his important essay *Ideology and Ideological State Apparatuses* (1984[1971]), Althusser analyzed ideology in terms of the process by which individuals come to understand and relate to themselves in a manner, which supports dominant class relations. According to Althusser, ideology provides an imaginary identity, an imagined map for locating oneself in the wider social network. Echoing Lacan, Althusser uses the notion of the mirror stage to deconstruct ideology. There is a duplicate mirror structure at the heart of ideology says Althusser, a structure that grants to the self an ideological mirror in which it can recognize itself and other people. Althusser calls this process 'interpellation' – the capturing of the individual within the net of received social meanings.

The Lacanian/Althusserian account of the decentering of the subject has been highly influential in recent sociological theory, and has impacted upon debates concerning agency, structure, class, social fragmentation, and cultural order. The social-theoretical work of Paul Hirst, Barry Hindess, Stuart Hall, Etienne Bailbar, Pierre Machery, Fredric Jameson, and Slavoj Zizek is, in differing ways, indebted to the Lacanian/Althusserian theory of the subject and its ideological subjection.

Feminism, Postmodernism, and Psychoanalytic Sociology

It is not only in studying politics and social change that psychoanalysis has become an important theoretical tool for sociology, but also in debates concerning gender and sexual politics Freudian ideas have been incorporated into social theory. In the sociology of sexuality, the sociology of the family, and especially the social theory of gender transformation, Freudian psychoanalysis has played a vital role in expanding sociologists' understanding of the subjective and affective components of human social relationships.

The psychoanalytic perspective made a forceful entry into contemporary feminist sociological theory in Juliet Mitchell's pioneering book, *Psychoanalysis and Feminism* (1974). Mitchell deployed Freudian and Lacanian psychoanalytic ideas as a means of connecting a discussion of gender power with an Althusserian/Marxist theory of late capitalist society. Against this theoretical backdrop, she asserted that definitions of masculinity and femininity are framed through linguistic and historical structures – with man as a self-determining, autonomous agent, and woman as a lacking other. Such gender dualism, according to Mitchell, is highly conducive to capitalist social regulation – the split between private and public, the pathologies of the familial life, and the like. Mitchell's ideas, while criticized in some feminist sociological circles, had a lasting impact on psychoanalytically oriented feminist sociology. Especially in terms of Lacanian feminist approaches, the writings of authors such as Julia Kristeva, Luce Irigaray, Jacequline Rose, and Judith Butler have significantly influenced sociological debate in recent years.

In the United States, the feminist theories of Nancy Chodorow, Jessica Benjamin, and Jane Flax have been influential in contemporary sociology. These feminist authors draw from the psychoanalytic perspective, but rather than turn to Lacan and French psychoanalysis their work selectively incorporates the insights of Freudian and post-Freudian (especially object-relational) theory. In Chodorow's work, it is part of an attempt to understand the psychic components of female and male socialization, especially in terms of the unconscious forces that shape gender roles. In Benjamin's work, psychoanalysis is deployed to rethink the dynamics of domination and submission within the wider frame of gender, society, and history. In Flax's discussion of psychoanalysis, feminism, and postmodernism, it is primarily a set of philosophical observations about the development of gender relations and the sociology of sexuality and intimacy.

Related to the intertwining of psychoanalysis and feminism, postmodernist appropriations of psychoanalysis have also been influential in recent sociological interventions. This has been especially true for the contested modernity/postmodernity debate, in which sociologists as diverse as Anthony Giddens, Alaine Touraine, and Zygmunt Bauman have drawn from Freud to analyze anew the self and self-identity. In the writings of Michel Foucault, Jean-Francois Lyotard, and Jacques Derrida, which have also had a strong influence on sociological theory, there has been much debate about the fate of the individual or 'death of the subject' in postmodernist culture. In all of these discussions, psychoanalysis has provided sociology with conceptual tools for questioning and deconstructing the enlightenment and rationality of progress.

Current Trends in European Psychoanalysis and Psychoanalytic Sociology

Let us now turn to consider, finally, some current trends in European psychoanalysis, trends that have impacted in various ways upon the development and deepening of psychoanalytic sociology.

Cornelius Castoriadis: Radical and Social Imaginaries

The late European psychoanalyst and social theorist Cornelius Castoriadis has articulated a theory of imagination – at once psychic and social – that has powerfully impacted upon some versions of sociology and social theory. Castoriadis's reflections on the imaginary principally concern the complex ways in which a world (at once emotional and social) somehow or

other comes to be ordered and organized from groundlessness or chaos. In *The Imaginary Institution of Society* (1987), Castoriadis argues that fantasy is a site of multiple, fractured and contradictory positionings of the individual in relation to self, to other people and to society and history. He claims that the psyche is continually elaborating representations and fantasies; as the flow of representations are produced, so new positionings of self and other are defined, which in turn leads to newer forms of fantasy, identification and cultural association. There is for Castoriadis a delicious indeterminacy at the heart of the Freudian unconscious, such that the regulative hierarchies of self, sexuality, gender, and power are constantly rearranged and sometimes transformed, at least partially as a consequence of this ceaseless psychic flux.

At its simplest Castoriadis's emphasis on the creative nature of the imagination underscores the permutation of fantasies and identifications that selves produce endlessly in relation to society and history. We insert ourselves, through the psychic flux of imagination, at one and the same moment as both creator and created, self and other, identity and difference; we draw on existing social institutions and cultural conventions to produce new images of self and society, which in turn feeds back into the cycle of representations. In all this, Castoriadis's central theme is creativity – of the individual self and the broader society. Underlining creativity, Castoriadis's theoretical position is a far cry from the insipid, commercially constructed notion of the 'ever-new' in popular culture. What distinguishes Castoriadis's position from popular understandings of creativity is his stress on the open ended and ambivalent nature of psychic representation and cultural production, and it is this stress, which necessarily involves reflecting on the more distressing aspects of violence, aggression, and destruction in contemporary culture. "Creation", writes Castoriadis, "does not necessarily – nor even generally – signify 'good' creation or the creation of 'positive values'. Auschwitz and the Gulag are creations just as much as the Parthenon and the *Principia Mathematica*" (Cornelius Castoriadis, *Philosophy, Politics, Autonomy*, Oxford: Oxford UP, 1991: pp. 3–4). It is hard – says Castoriadis – to grasp, and harder to understand, that sociopolitical paths or fields of imagination stretch all the way from progressive politics to fanaticism and fascism. But the search for alternative futures and the search for autonomy and justice are among the creations in Western history that people value highly and judge positively; the practice of critique, of putting things into question, forms a common starting point for a radical challenge to received social and political meanings.

Castoriadis (1989), following Freud, contends that originary fantasy and representation underlies the capacity of the subject for critical self-reflection and autonomy. As he says of psychoanalysis itself: 'the possibility of representing *oneself as* representational activity and of putting oneself in question as such is not just a philosophical subtlety; it corresponds to the *minimum* we require of every patient when we try to lead him or her to discover that X is not Y but that it is very much so for *his* or *her* own representational activity and that there may be reasons for this' (1989: p. 27). Representation, unconscious flux, and originary fantasmatization: these are, says Castoriadis, necessary conditions for the possibility of reflectiveness in the individual human subject.

Julia Kristeva: Imagination Reassessed

Julia Kristeva, Professor of Linguistics at the University of Paris VII, did her psychoanalytic training with Lacan. Already in her earliest theoretical work, however, she indicated a determination to move beyond the conceptual terrain of Lacanianism narrowly defined. For example, her doctoral dissertation, which was subsequently published as her first book *Revolution in Poetic Language*, blends linguistics and psychoanalytical theory to advance a novel account of how preverbal experience – infantile, maternal, and poetic – enters into, shapes, distorts, and disrupts language through processes of art, literature, and psychoanalysis. In her more recent work, Kristeva has turned away from Lacan and back to classical Freudianism, and especially toward Kleinian psychoanalysis.

According to Kristeva, the psychic work of representation is a universal feature 'present in all psychic activities and behaviors', and is by no means restricted to the therapeutic relationship, nor to particular aspects of mental functioning, such as the standard psychoanalytic menu of daydreaming or erotic imaginings. Rather, it is our ordinary experiences – from sporting activities to the practicalities of learning and education – that are saturated with this originary imagination. All psychic activity, says Kristeva, is 'impregnated with fantasies'. What is clear in Kristeva's account of fantasy, is that this imaginary domain is inextricably interwoven with the motions of pleasure and unpleasure, the most primitive impulses of desire and aggressiveness which bring a world of subjectivity into being in the first place. Freud astutely captured the theatrical dynamics of sensational life in terms of the logics of dreaming; and it is these affective processes (the dream work), which for Kristeva dominate the mental apparatus from start to finish. Yet what might Kristeva be gaining by drawing attention to the imaginary resilience – the creative representational refashioning of the senses – of everyday life? And what, we might ask, is gained by thinking of what happens to our wishes (inseparable from figure and fantasy) in categories that emphasize the prolinguistic: fantasy life is "expressed in and dealt with by *mental processes far removed from words* and conscious relational thinking".

Kristeva conceptualizes what she refers to as the 'proto-fantasy' as a kind of oscillation of the imagination, with the human subject internally divided, split between infantile narcissism and the other's lack. Strictly speaking, if representation is an 'active presence of fantasy scenes', this is because desire, for Kristeva as for Lacan, is the desire of the Other. To desire the Other is a kind of fashioning, an imagining of what the other dreams, an imitating, an identification with the other's desire. Notwithstanding that it is the inescapability of imaginary misrecognition that leaves the human subject to impute an imaginary fullness to the other's desire which, in fact, pertains only to the representation (i.e., the imaginary plenitude that the subject itself desires), the point is there would be no meaning, not to say anything of the possibility for self-knowledge, without these imaginative fashionings.

Kristeva has written in great depth about the length people will go to in creating obstacles to pleasure; in doing so, she has reformulated Freud's account of Oedipal desire as a general theory of the constitution of the subject and its Baroque imaginings. What is significant to sociology here is that

Kristeva's reflections on the unconscious or preconscious fantasy captures something important about the imaginary making and taking of pleasure in daily life. In Kristeva's reckoning, the psychoanalytic theory of fantasy is about the human subject's imaginings that inform, say, perceptions of the body, imaginings about how one sounds and speaks, imaginings about one's sporting prowess, imaginings about pop stars and celebrities, imaginings about educational advancement and intellectual recognition, and imaginings about where one is headed or what may be wrong with one's life.

More than any other psychoanalyst, perhaps more than Freud's foundational insights, Kristeva captures the complex ways people use their imagination to make life meaningful. For Kristeva, individuals are captured by, and in thrall to, their unconscious fantasies – these radically strange, foreign social dreams. Such fantasies, in addition to constituting intercourse between unconscious dreams and practical life, are the very imaginings of imagination.

Jean Laplanche: Imaginary Seductions

Jean Laplanche trained with Lacan, and his early writings indicate a strong conceptual debt to his former analyst. Indeed, the book for which Laplanche is perhaps best known in the Anglo-American world is *The Language of Psychoanalysis* (1973), coauthored with J.B. Pontalis – an encyclopedic coverage of core psychoanalytic concepts through the lens of French Freudianism. Further works of psychoanalytic exposition and critique followed, including the influential tract *Life and Death in Psychoanalysis* (1976), in which Laplanche struggled to remain faithful to the Lacanian modifications to psychoanalysis, principally through expressing his general suspicion of structural theory. It seems likely, however, that Laplanche's lasting contribution to psychoanalysis derives from his reflections on otherness in the formation of human subjectivity, as developed in his 'general theory of seduction', set out in the five-volume *Problématiques* (1980–87).

Laplanche was one of the first post-Lacanians to write of the strange transformations – the condensations, displacements, and reversals – of unconscious repression, which results in the formation of an internal foreign other, of what Freud called a thing-presentation, or the depths of imagination itself. He has been one of the few major psychoanalytic thinkers, period, to focus on the irreducible creativity of unconscious work, by which he means specifically the field of symbolizing activity. His psychoanalytic work, to a considerable degree, represents a series of reflections on the ontology of determinism within Freudianism. Laplanche's account of the internal otherness – an unconscious of strange, foreign bodies – is foregrounded as at the core of psychic life. As he writes:

> What guarantees the alien-ness of the other? Can one affirm here, with Lacan, the priority of language? If for my part, I speak rather of a "message", this is for at least two well-defined reasons: *firstly*, the message can just as easily be non-verbal as verbal; and for the baby it is principally non-verbal. *Secondly*, emphasising "language" effaces the alterity and individuality of the other in favour of transhistorical structures.
>
> (Laplanche, 1997: p. 660)

Laplanche, like Kristeva, rejects the linguistic imperialism of Lacanian doctrine: "the message can just as easily be nonverbal as verbal". So too, like Kristeva, Laplanche distances himself from a concern with 'transhistorical structures' (phylogenesis, language) in favor of the essential uniqueness and individuality of human imagination. In shifting away from Lacan and back to Freud – returning to prelinguistic psychical representatives or fantasmatic constructions made of images and split from words – Laplanche will emphasize that in the act of *psychic translation* the singular individual *creates* in the strongest sense of the term.

It could be said that Laplanche is out to provide a social theory of our *struggle for representation* in the field of symbolizing activity – which, in a sense, has been the subject of all psychoanalytic theories since Freud unearthed the unconscious logics of the dream. For in his preoccupation with the problem of translation – by which is meant the psychic force field of representations, resemblances, contiguities, condensations, and reversals – Laplanche's work plays ingeniously on a subtle, but definite, relation between human subjects in the context of symbolic and social formations. For Laplanche, it is essential to grasp that the infant is, from the beginning of life, presented with what he calls 'messages' (both verbal and nonverbal) by parents, messages which the infant is ill-equipped to adequately deal with or understand on an emotional plane. It makes perhaps less difference what the soft caresses of a mother actually signify as regards the self-understandings of the adult, though part of Laplanche's interest turns on the way parents always convey far more than they consciously intend. What matters in Laplanche's scheme is that the infant has been addressed or called with a message, a message that is at once exciting and mystifying.

The striking feature of Laplanche's theorization of the message as enigmatic is its sheer open-endedness. His account of the psychosexual development of the individual subject in terms of the ongoing emotional work of translation a retranslation would make no sense were it not for the recognition that, because of the small infant's initially limited ways of trying to emotionally process proffered messages, psychic life is always, necessarily, imaginative, creative, and inventive. Unlike the iron determinism of the early Lacan's emphasis on the Symbolic subjection of the subject, it is the mystifying element of the message that for Laplanche sparks imaginative associations in the child. What is inescapable for the infant – and then subsequently for the adult – is that such mystifying messages demand continual psychic work are in need of continual translation. Indeed, Laplanche himself has acknowledged that he came up with the concept of 'message', with all this implies of the need for translation, in order to overcome the rigid determinism of psychoanalysis in France since Lacan.

Concluding Remarks

Castoriadis, Kristeva, and Laplanche are not alone among those theorists of the contemporary age who have wrestled with the question of imagination as well as individual and social transformations affecting imaginary life. Fortunately, for academic social science but also for the demands of sociology, there have been a growing number of voices raising pressing

political issues about the conditions and consequences of our imaginative interpersonal relations in a postmodern world of fragmentation and fracture. Such authoritative voices today include, to mention only a few: Judith Butler, Drucilla Cornell, Slavoj Zizek, Homi Bhabha, Christopher Bollas, Lynne Segal, Fredric Jameson, Charles Lemert, Luce Irigaray, Elizabeth Grosz, Nancy Chodorow, Jane Flax, Charles Spezzano, Thomas Ogden, and Jessica Benjamin. Each has drawn from psychoanalysis to develop a particular angle on the changing relations between self and society in the contemporary epoch. Each has focused on specific problematics of current social conditions – from feminism to postmodernism, from psychotherapy to literature – in rethinking the terms of both individual and collective imaginaries. Psychoanalysis, it transpires, continues to provide vital food for thought to sociology in the early years of the twenty-first century.

Abstract

Psychoanalysis was first developed by Sigmund Freud beginning in the late 1890's in Europe as a theory of mental development, a theory of the nature of pathological mental processes, and a method of treatment for psychiatric disorders. Freud's theoretical work was followed by a body of psychoanalytic theory contributions referred to as ego psychology which was then followed by bodies of work known as object relations and self-psychology. Freud believed that psychopathology has its origins in mental processes which are generally outside of the individual's awareness as a result of the vicissitudes of development. Freud believed that these clues about the nature of the unconscious pathological processes could be gained from a variety of sources including the analysis of the patient's dreams and of the patient's transference with the psychoanalyst. The transference was described as a reawakening of early developmental conflicts in the relationship with the psychoanalyst. Further the two major schools of modern psychotherapy, psychoanalytic psychotherapy and cognitive behavioral psychotherapy are based on the same important premise that psychopathology has its origins in developmental and interpersonal processes and that the pathological functions operate in an unconscious manner. This chapter highlights important aspects of psychoanalytic theories of both development and treatment with a particular focus on the use of transference within the treatment process.

Psychoanalysis is (1) a personality theory, and, more generally, a theory of psychological development and functioning that focuses particularly on unconscious mental processes; (2) a method for the investigation of psychological functions based on the exploration of the patent's verbal and nonverbal productions within a special therapeutic setting; and (3) a method for treatment of a broad spectrum of psychopathological conditions, which at one time or the other over the second half of the twentieth century was prescribed for the symptomatic neuroses (anxiety states, depression, obsessive–compulsive disorder, conversion hysteria, and dissociative hysterical pathology), sexual inhibitions and perversions ('paraphilias'), and the personality disorders. Psychoanalysis has also been applied, mostly in modified versions, in psychoanalytic psychotherapies, to the treatment of many psychiatric illnesses named above as well as severe personality disorders, psychosomatic conditions, and certain psychotic conditions, particularly a subgroup of patients with chronic schizophrenic illness.

At the present time, psychoanalysis is not considered a first-line treatment for most psychiatric conditions, in large part due to the cost and time requirements of psychoanalysis, although the major psychotherapeutic approaches in use today, namely psychoanalytic and cognitive–behavioral therapies, are based on psychoanalytic concepts. Both psychoanalytic psychotherapies and cognitive–behavioral psychotherapies are based on a version of the vicissitudes of both normal and pathological mental development embodied in psychoanalytic theories of development. And, both approaches are based on an identical assumption that psychopathology has its origins in developmental and interpersonal processes, and that the pathological functions operate essentially in an unconscious manner. While the *language* that describes both the unconscious processes and the techniques used in treatment also differ between these two approaches, and while there is some difference in emphasis on cognitive and affective processes, the goals and actual techniques of both treatment approaches are parallel to psychoanalysis, which are to bring the pathological unconscious processes into awareness so they can be remediated. The goals of psychoanalytic treatment, although, are the most far reaching, both in breadth and depth of mental processes that are the subject for understanding and remediation through treatment.

Freud's Theory of the Mental Apparatus

Freud's (1953a) starting point was his study of hysterical patients and the discovery that, when he found a way to help these patients piece together a coherent account of the antecedents of their conversion symptoms, dissociative phenomena, and pathological affective dispositions, all these psychopathological phenomena could be traced to traumatic experiences in their past that had become unconscious. In the course of a few years, Freud abandoned his early efforts to recover repressed material by means of hypnosis, and replaced hypnosis with the technique of 'free association,' an essential aspect of psychoanalytic technique until the present time.

Practicing this method led Freud to several lines of discovery: to begin, he conceptualized unconscious mechanisms of defense that opposed the recovery of memories by free association. He described these mechanisms to include repression, negation, isolation, projection, introjection, transformation into the opposite, rationalization, intellectualization, and most important, reaction formation. The latter involves overt, chronic patterns of thought and behavior that serve to disguise and disavow consciously experienced conflicted emotions by experiencing the opposite emotion consciously. The discovery of reaction formations led Freud to the psychoanalytic study of character pathology and normal character formation, and still constitutes an important aspect of

the contemporary psychoanalytic understanding and treatment of personality disorders (for practical purposes, character pathology and personality disorders are synonymous concepts).

A related line of development in Freud's theories was the discovery of the differential characteristics of conscious and unconscious thinking. This set of concepts came to be known as the topographic theory. Freud differentiated conscious thinking, the 'secondary process,' invested by 'attention cathexis' and dominated by sensory perception and ordinary logic in relating to the psychosocial environment, from the 'primary process' of the 'dynamic unconscious.' That part of the unconscious mind he referred to as 'dynamic' exerted constant pressure or influence on conscious processes, against the active barrier constituted by the various defensive operations, particularly repression. The dynamic unconscious, Freud proposed, presented a general mobility of affective investments, and was ruled by the 'pleasure principle' in contrast to the 'reality principle' of consciousness. The 'primary process' thinking of the dynamic unconscious was characterized by the absence of the principle of contradiction and of ordinary logical thinking, the absence of negation and of the ordinary sense of time and space, the treatment of a part as if it were equivalent to the whole, and a general tendency toward condensation of thoughts and the displacement of affective investments from one to another mental content.

Finally, Freud proposed a 'preconscious,' an intermediate zone between the dynamic unconscious and consciousness. It represented the storehouse for retrievable memories and knowledge and for affective investments in general, and it was the seat of daydreaming, in which the reality principle of consciousness was loosened, and derivatives of the dynamic unconscious might emerge. Free association, in fact, primarily tapped the preconscious, as well as the layer of unconscious defensive operations which oppose the emergence of material from the dynamic unconscious.

This model of the mind as a 'place' with unconscious, preconscious, and conscious 'regions' thus constituted the topographic model, although Freud eventually supplanted it with the 'structural theory,' namely the concept of three interacting psychic structures, the ego, the superego, and the id (Freud, 1961).

The Id

The id is the mental structure that contains the mental representatives of the 'drives'; that is, the ultimate intrapsychic motivations that Freud (1955) described in his final, 'dual drive theory' of libido and aggression, or metaphorically, the sexual or life drive and the destruction or death drive. In exploring unconscious mental processes, what at first appeared to be specific traumatic life experiences turned out to reflect surprisingly consistent, repetitive, intrapsychic experiences of a sexual and aggressive nature.

Freud (1953a) was particularly impressed by the regularity with which his patients reported the emergence of childhood memories reflecting seductive and traumatic sexual experiences on the one hand, and intense sexual desires and related guilt feelings, on the other. He discovered a continuity between the earliest wishes for dependency and being taken care of (the psychology, as he saw it, of the baby at the mother's breast) during what he described as the 'oral phase' of development; the pleasure in exercising control and struggles around autonomy in the subsequent 'anal phase' of development (the psychology of toilet training); and, particularly, the sexual desire toward the parent of the opposite gender and the ambivalent rivalry for that parent's exclusive love with the parent of the same gender. He described this latter state as characteristic of the 'infantile genital stage' (from the third or fourth to the sixth year of life) and called its characteristic constellation of wishes and conflicts the positive Oedipus complex. He differentiated it from the negative Oedipus complex, that is, the love for the parent of the same gender, and the corresponding ambivalent rivalry with the parent of the other gender. Freud proposed that oedipal wishes came to dominate the earlier infantile hierarchy of oral and anal wishes, becoming the fundamental unconscious realm of desire.

Powerful fears motivated the repression of awareness of infantile desire: the fear of loss of the desired person (the individual toward whom the emotional impulse, or drive, is directed is called the 'object' in the original English translation), and later of the loss of the object's love was the basic fear of the oral phase, directed against libidinal wishes to possess the breast; the fear of destructive control and annihilation of the self or the object was the dominant fear of the anal phase directed against libidinal wishes of anal expulsion and retentiveness, and the fear of castration, 'castration anxiety,' the dominant fear of the oedipal phase of development, directed against libidinal desire of the oedipal object. Unconscious guilt was a dominant later fear, originating in the superego as that set of functions developed around the second year of age and generally directed against drive gratification (see Section The Superego). Unconscious guilt over sexual impulses unconsciously equated with oedipal desires constituted to Freud a major source of many types of pathology, such as sexual inhibition and related character pathology.

Freud believed the infants biological status and its changes served as the impetus for the development of mental functions, and described the oral phase as essentially coinciding with the infantile stage of breast feeding, the anal phase as coinciding with struggles around sphincter control, and the oedipal stage as developing gradually during the second and through the fourth years, and culminating in the fourth and the fifth years of life. This latter phase would then be followed by more general repressive processes under the dominance of the installation of the superego, leading to a 'latency phase' roughly corresponding to the school years, and finally, to a transitory reactivation of all unconscious childhood conflicts under the dominance of oedipal issues during puberty and early adolescence. Erik Erikson later expanded Freud's description of developmental phases through adolescence to a series of adult developmental phases, and his contribution met with general acceptance.

The drives represent for human behavior what the instincts constitute for the animal kingdom, that is, the ultimate biological motivational system. The drives are constant, highly individualized, developmentally shaped motivational systems. Under the dominance of the drives and guided by the primary process, the id exerts an ongoing pressure toward gratification, operating in accordance with the pleasure principle. Freud

initially equated the drives with primitive affects. After discarding various other models of unconscious motivation, he ended up with the dual drive theory of libido and aggression.

He described the libido or the sexual drive as having an 'origin' in the erotogenic nature of the leading oral, anal, and genital bodily zones; an 'impulse' expressing the quantitative intensity of the drive by the intensity of the corresponding affects; an 'aim' reflected in the particular act of concrete gratification of the drive; and an 'object' consisting of displacements from the dominant parental objects of desire.

The introduction of the idea of an aggressive or 'death' drive, arrived at later in Freud's writing, stemmed from his observations of the profound self-destructive urges particularly manifest in the psychopathology of major depression and suicide, and of the 'repetition compulsion' of impulse driven behavior that frequently seemed to run counter to the pleasure principle that supposedly governed unconscious drives. He never spelled out the details of the aggressive drive as to its origins. Freud described drives as intermediate between the body and the mind; the only thing we knew about them, Freud (1957a) suggested, were 'representations and affects.'

The Ego

While the id is the seat of the unconscious drives, and functions according to the 'primary process' of the dynamic unconscious, the ego, Freud (1961) proposed, is the seat of consciousness as well as of unconscious defense mechanisms that, in the psychoanalytic treatment, appear as 'resistance' to free association. The ego functions according to the logical and reality-based principles of 'secondary process,' negotiating the relations between internal and external reality. Guided by the reality principle, it exerts control over perception and motility; it draws on preconscious material, controls 'attention cathexes,' and permits motor delay as well as selection of imagery and perception. The ego is also the seat of basic affects. Freud particularly focused his attention on anxiety, which he viewed as an alarm signal against the psychologically experienced danger of emergence of unconscious, repressed, and conflicted impulses. This alarm signal may turn into a disorganized state of panic when the ego is flooded with external perceptions that activate unconscious desire and conflicts, or with overwhelming, traumatic experiences in reality that resonate with such repressed unconscious conflicts, and overwhelm the particularly sensitized ego in the process.

Freud originally equated the 'I,' that is, the categorical self of the philosophers, with consciousness. Later, once he established the theory of the ego as an organization of both conscious and unconscious functions, he at times treated the ego as if it were the subjective self, and at other times, as an impersonal organization of functions. Out of this ambiguity evolved the contemporary concept of the self within modern ego psychology as well as in British and American object relations and cultural psychoanalytic contributions (Kernberg, 1984).

An alternative theory of the self was proposed by Kohut (1971), the originator of the self-psychology approach within contemporary psychoanalysis. Kohut's work was controversial within psychoanalysis in part because he discarded the structural theory on which psychoanalysis had been historically based. He replaced the three 'structures' that what he called the 'bipolar self.' The self, to Kohut, emerged from two primitive sets of functions that served to maintain psychological equilibrium. The first was called the idealized parental imago, a set of internal representations of the omnipotent and all caring parent on whom security, and even life, relied. The second was the grandiose self, representing an internalization of the idealized parent into the self. Kohut believed these two structures transformed as development proceeded into adult capacities and psychological abilities that maintained psychological equilibrium, self-cohesion he called it, self-awareness and reflection, and a wide range of adaptive functions. Another controversial view of Kohut was his later diminution of the importance of the oedipal phase of development in health and psychopathology in favor of an emphasis on pre-oedipal development.

Kohut's work drew heavily on the school of thought that came to be known as object relations theory, first promulgated by Melanie Klein in the 1930s. Klein and those who followed her and elaborated on her theories emphasized to a much greater extent than Freud the importance of the years before the oedipal phase for psychological development and the origins of psychopathology. Freud emphasized the role of trauma in derailing normal early developmental processes, but the object relations theorists emphasized a much broader perspective, positing that early psychological development was immensely influenced by the nature of the mother–infant psychological attachment (in the present, one would say not only the attachment to the mother but to anyone playing a substantial role in early nurturance and care) and the resulting internalized perceptions of the self and parent. In this view, not only trauma, but also the vagaries of the typical and individually unique attachment exerted a powerful and determinative effect on the infant's psychological development, interacting with the inborn characteristics of the infant (such as introversion/extroversion, risk aversion/risk taking, and passivity/aggressiveness).

Nowadays, an integrated concept of the self as the seat of subjectivity is considered an essential structure of the ego, and the concept of 'ego identity' refers to the integration of the concept of the self. Because developmental processes in early infancy and childhood are now better understood, an integrated self-concept usually goes hand in hand with the capacity for an integrated concept of significant others. An unconscious tendency toward primitive dissociation or 'splitting' of the self-concept and of the concepts of significant objects runs counter to such integration.

Character, or personality, from a psychoanalytic perspective, may be defined as constituting the behavioral aspects of ego identity (the self-concept) and the internal relations with significant others (the internalized world of 'object relations'). The sense of personal identity and of an internal world of object relations in turn reflects the subjective side of character. It was particularly the ego psychological approach – one of the dominant contemporary psychoanalytic schools which emerged in the 1930's – that developed the analysis of defensive operations of the ego, and of pathological character formation as a stable defensive organization that needed to be explored and resolved in the psychoanalytic treatment. In the process, ego psychology importantly contributed to the

psychoanalytic understanding of mental functioning and had a significant impact on psychoanalytic treatment. This school of thought posited that all conscious mental processes, including free association were influenced by ego actions, and that the understanding of ego functions could be both revealed in the patient's verbal productions, and well as serve as a focus for the therapeutic action of psychoanalysis.

Freud (1957c) conceptualized narcissism as the libidinal investment of the ego or self, in contrast to the libidinal investment of significant others ('objects'). In proposing the possibility of a withdrawal of libidinal investment from others with an excessive investment in the self as the basic feature of narcissistic pathology, he pointed to a broad spectrum of psychopathology, and thus first stimulated the contribution of Abraham (1919), and later those of Grunberger (1979), Jacobson (1964), Kernberg (1975), Klein (1957), Kohut (1971), and Rosenfeld (1987). Thus crystallized the description of the narcissistic personality as a disorder derived from a pathological integration of a grandiose self as a defense against unbearable aggressive conflicts, particularly around primitive envy.

The Superego

In his analysis of unconscious intrapsychic conflicts between drive and defense, Freud regularly encountered unconscious feelings of guilt in his patients, reflecting an extremely strict, unconscious infantile morality, which he called the superego. This unconscious morality could lead to severe self-blame and self-attacks, and particularly to abnormal depressive reactions, which he came to regard as expressing the superego's attacks on the ego. It was, particularly, in studying normal and pathological mourning that Freud (1957c) arrived at the idea of excessive mourning and depression as reflecting the unconscious internalization of the representation of an ambivalently loved and hated lost object. In unconsciously identifying the self with that object introjected into the ego, the individual now attacked his own self in replacement of the previous unconscious hatred of the object; and the internalization of aspects of that object into the superego reinforced the strictness of the individual's preexisting unconscious infantile morality.

Freud traced the origins of the superego to the overcoming of the Oedipus complex via unconscious identification with the parent of the same gender: in internalizing the oedipal parent's prohibition against the rivalry with him or her and the unconscious death wishes regularly connected with such a rivalry, and against the incestuous desire for the parent of the other gender, this internalization crystallized an unconscious infantile morality. The superego, thus based upon prohibitions against incest and parricide, and a demand for submission to, and identification with the oedipal rival, became the guarantor of the capacity for identification with moral and ethical values in general.

Freud also described the internalization of the idealized representations of both parents into the superego in the form of the 'ego ideal.' He suggested that the earliest sources of self-esteem, derived from mother's love, gradually fixated by the baby's and small child's internalizations of the representations of the loving mother into the ego ideal, led to the parental demands also becoming internalized. In other words, normally self-esteem is maintained both by living up to the expectations of the internalized idealized parental objects and by submitting to their internalized prohibitions. This consideration of self-esteem regulation leads to the clinical concept of narcissism as normal or pathological self-esteem regulation, in contrast to the theoretical concept of narcissism as the libidinal investment of the self.

Psychoanalytic Treatment

The Psychoanalytic Theory of Psychopathology

This theory proposes that the clinical manifestations of the symptomatic neuroses, character pathology, perversions, sexual inhibitions, and selected types of psychosomatic and psychotic illness reflect unconscious intrapsychic conflicts between drive derivatives following the pleasure principle, defensive operations reflecting the reality principle, and the unconscious motivations of the superego. Unconscious conflicts between impulse and defense are expressed in the form of structured conflicts between the agencies of the tripartite structure. There are ego defenses against impulses of the id; the superego motivates inhibitions and restrictions in the ego; at times, the repetitive, dissociated expression of id impulses ('repetition compulsion') constitutes an effective id defense against superego pressures. The resolution of unconscious conflicts implies the analysis of all these intersystemic conflicts.

All these conflicts are clinically expressed by three types of phenomena: (1) inhibitions of normal ego functions regarding sexuality, intimacy, social relations, and affect activation; (2) compromise formations between repressed impulses and the defenses directed against them; and (3) dissociative expression of impulse and defense. This latter category implies a dominance of the splitting mechanisms referred to before. These have acquired central importance in the understanding of severe character pathology as reflected in contemporary psychoanalytic thinking. The concept of developmental deficit has also been widely used to describe the view that it may be not only a conflict, but also a lack of developmental maturation, even in the absence of major conflict, which may also both contribute to psychopathology and serve as a focus for remediation through treatment.

The Structural Formulation of the Psychoanalytic Method

Psychoanalytic treatment consists, in essence, in facilitating the reactivation of the pathogenic unconscious conflicts in the treatment situation by means of a systematic analysis of the defensive operations directed against them. In so doing, the treatment may address barriers to normal development, which deficits may also be addressed as issues for attention on their own (see following section below for further discussion). This leads to the gradual emergence of repressed impulses, with the possibility of elaborating them in relation to the analyst (through the emergence of transference), and their eventual adaptive integration into the adult ego. Freud (1953c) had described the concept of 'sublimation' as an adaptive transformation of unconscious drives: drive derivatives, converted into a consciously tolerable form, are

permitted gratification in a symbolic way, while their origin remains unconscious. The result of this process is an adaptive, nondefensive compromise formation between impulse and defense. In analysis, the gradual integration into the patient's conscious ego of unconscious wishes and desires from the past and the understanding of the fantasized threats and dangers connected with them facilitates their gradual elaboration and subliminatory expression both in the consulting room and in everyday life.

The Object Relations Theory Formulation of Psychoanalytic Treatment

In the light of contemporary object relations theory, the formulation based upon the structural theory (resolution of unconscious conflicts between impulse and defense) has changed, in the sense that all unconscious conflicts are considered to be imbedded in unconscious internalized object relations. Such internalized object relations determine both the nature of the defensive operations and of the impulses against which they are directed. These internalized object relations constitute, at the same time, the 'building blocks' of the tripartite structure of id, ego, and superego. Object relations theory proposes that the gradual analysis of intersystemic conflicts between impulse and defense (structured into conflicts among ego, superego, and id) decomposes the tripartite structure into the constituent conflicting internalized object relations. These object relations are reactivated in the treatment situation in the form of an unconscious relation between self and significant others replicated in the relation between patient and analyst; that is, the 'transference.' Transference is not, as described in the common parlance, a unitary response, but a multilayered and multifocal set of responses and perceptions.

The transference is the unconscious repetition in the 'here and now' of unconscious, conflicting pathogenic relationships from the past. The transference reflects the reactivation of the past conflict not in the form of a memory, but in the form of a repetition. This repetition provides essential information about the past, but constitutes at the same time a defense in the sense that the patient repeats instead of remembering. Therefore, transference has important informative features that need to be facilitated in their development, and defensive features that need to be therapeutically resolved once their nature has been clarified. Transference analysis is the fundamental ingredient of the psychoanalytic treatment.

The Psychoanalytic Treatment Process

Gill (1954), in a classical definition that is still relevant today, proposed the definition of psychoanalysis as a treatment that facilitates the development of a 'regressive transference neurosis' and its resolution by means of interpretation alone, carried out by the analyst from a position of technical neutrality.

The concept of a regressive transference neurosis refers to the gradual gathering into the relationship with the analyst of the patient's most important past pathogenic experiences and unconscious conflicts. The concept of a regressive transference neurosis has been largely abandoned in practice because, particularly in patients with severe character pathology, transference regression occurs so early and consistently that the gradual development of a regressive transference neurosis is no longer a useful concept.

Gill's proposal that the resolution of the transference be achieved 'by interpretation alone' refers to 'interpretation' as a set of the psychoanalyst's interventions that starts with 'clarification' of the patient's subjective experiences communicated by means of free association, expands with the tactful 'confrontation' of aspects of the patient's patterns of behavior that are expressed in a dissociated or split-off manner from his subjective awareness, and thus complements the total expression of his intrapsychic life in the treatment situation, and finally evolves into 'interpretation per se.' Interpretation per se implies the formulation of hypotheses regarding the unconscious meanings in the 'here and now' of the patient's material, and the relation of these unconscious meanings with the 'there and then' of the patient's unconscious, past pathogenic experiences.

The concept of 'technical neutrality' refers to the analyst's impartiality regarding both impulse and defense, with a concerned objectivity that provides a helpful collaboration with the patient's efforts to come to grips with his intrapsychic conflicts.

This definition of the nature of psychoanalytic treatment needs to be complemented with the contemporary concepts of 'transference,' 'countertransference,' 'acting out,' and 'working through.'

An Object Relations Theory Model of the Transference and Countertransference

Modern object relations theory proposes that, in the case of any particular conflict around sexual or aggressive impulses, the conflict is imbedded in an internalized object relation, that is, in a repressed or dissociated representation of the self ('self-representation') linked with a particular representation of another who is a significant object of desire or hatred ('object representation'). Such units of self-representation, object representation, and the dominant sexual, dependent, or aggressive affect linking them are the basic 'dyadic units,' whose consolidation will give rise to the tripartite structure. Internalized dyadic relations dominated by sexual and aggressive impulses will constitute the id; internalized dyadic relations of an idealized or prohibitive nature the superego, and those related to developing psychosocial functioning and the preconscious and conscious experience, together with their unconscious, defensive organization against unconscious impulses, the ego.

These internalized object relations are activated in the transference with an alternating role distribution, that is, the patient enacts a self-representation while projecting the corresponding object representation onto the analyst at times, while at other times projecting his self-representation onto the analyst and identifying with the corresponding object representation. The impulse or drive derivative is reflected by a dominant, usually primitive affect disposition linking a particular dyadic object relation; the associated defensive operation is also represented unconsciously by a corresponding dyadic relation between a self-representation and an object representation under the dominance of a certain affect state.

The concept of countertransference, originally coined by Freud as the unresolved, reactivated transference dispositions of the analyst is currently defined as the total affective states of the analyst in response to the patient and his or her transference, shifting from moment to moment, and providing important data of information to the analyst. The countertransference, thus defined, may be partially derived from unresolved problems of the analyst, but stems as well from the impact of the dominant transference reactions of the patient, from reality aspects of the patient's life, and sometimes from aspects of the analyst's life situation, that are emotionally activated in the context of the transference developments. In general, the stronger the transference regression, the more the transference determines the countertransference; thus the countertransference becomes an important diagnostic tool. The countertransference includes both the analyst's empathic identification with a patient's central subjective experience ('concordant identification') and the analyst's identification with the reciprocal object or self-representation ('complementary identification') unconsciously activated in the patient as part of a certain dyadic unit, and projected onto the analyst (Racker, 1957). In other words, the analyst's countertransference implies identification with what the patient cannot tolerate in himself or herself, and must dissociate, project, or repress.

At this point, it is important to refer to certain primitive defensive operations that were described by Klein (1952) and her school as well as Kohut (1971) and his school in the context of the analysis of severe character pathology. Primitive defensive operations are characteristic of patients with severe personality disorders, and emerge in other cases during periods of regression. They include splitting, projective identification, denial, omnipotence, omnipotent control, primitive idealization, and devaluation (contempt). All these primitive defenses center on splitting; that is, an active dissociation of contradictory ego (or self) experiences as a defense against unconscious intrapsychic conflict. They represent regression to the phase of development (the first 2–3 years of life) before repression and its related mechanisms mentioned are established.

Primitive defensive operations present important behavioral components that tend to induce behaviors or emotional reactions in the analyst, which, if the analyst manages to 'contain' them, permit him to diagnose in himself projected aspects of the patient's experience. Particularly 'projective identification' is a process in which (1) the patient unconsciously projects an intolerable aspect of self-experience onto (or 'into') the analyst; (2) the analyst unconsciously enacts the corresponding experience ('complementary identification'); (3) the patient tries to control the analyst, who now is under the effect of this projected behavior; and (4) the patient meanwhile maintains empathy with what is projected. Such complementary identification in the countertransference permits the analyst to identify himself through his own experience with the aspects of the patient's experience communicated by means of projective identification. This information complements what the analyst has discovered about the patient by means of clarification and confrontation, and permits the analyst to integrate all this information in the form of a 'selected fact' that constitutes the object of interpretation. Interpretation is thus a complex technique that is very much concerned with the systematic analysis of both transference and countertransference.

Contemporary Trends of the Psychoanalytic Method

Contemporary psychoanalytic technique can be seen as having evolved from a 'one person psychology' into a 'two person psychology,' and then into a 'three person psychology.' The concept of 'one person psychology' refers to Freud's original analysis of the patient's unconscious intrapsychic conflicts by analyzing the intrapsychic defensive operations that oppose free association. The 'two person psychology' refers to the central focus on the analysis of transference and countertransference. In the views of the contemporary intersubjective, interpersonal, and self-psychology psychoanalytic schools, the relationship between transference and countertransference is mutual, in the sense that the transference is at least in part a reaction to reality aspects of the analyst, who therefore must be acutely mindful of his contribution to the activation of the transference. The so-called 'constructivist' position regarding transference analysis assumes that it is impossible for the analyst to achieve a totally objective position outside the transference/countertransference bind.

In contrast, the contemporary 'objectivist' position, represented by the 'three person psychology' approaches of the Kleinian school, the French psychoanalytic mainstream, and significant segments of contemporary ego psychology proposes that the analyst has to divide himself between one part influenced by transference and countertransference developments, and another part that, by means of self-reflection, maintains himself or herself outside this process, as an 'excluded third party,' who, symbolically, provides an early triangulation to the dyadic regression that dominates transference developments. This triangulation in the treatment situation becomes particularly important in the treatment of severe personality disorders.

The 'repetition compulsion' as a resistance of the id is very likely a form of acting out as a defense against emotional containment of an extremely painful or traumatic set of experiences. 'Working through' refers to the repeated elaboration of an unconscious conflict in the psychoanalytic situation. It is a major task for the analyst, who has to be alert to the subtle variation in meanings and implications of what on the surface may appear to be an endless repetition of the same conflict in the transference. The patient elaboration of the conflict that presents itself with these repetitive characteristics also implies the function of 'holding' originally described by Winnicott (1965) and later emphasized by Kohut. It consists of the analyst's capacity to withstand the onslaught of primitive transferences without retaliation, abandonment of the patient, or a self-devaluing giving up, and the maintenance of a working relationship (or 'therapeutic alliance') that addresses itself consistently to the healthy part of the patient, even when the latter is under the control of his most conflicting behaviors. Bion's (1967) concept of 'containing' is complementary to 'holding,' in the sense that holding deals mostly with the affective disposition of the analyst, and containing with his cognitive capacity to maintain a concerned objectivity and focus on the 'selected fact,' permitting the integration in the analyst's mind what the patient can only express in violently dispersed or split off behavior patterns. Kohut believed that an essential part

of the holding process is the analyst's empathic capacity and the communication of this understanding directly at the appropriate time to the patient. He also believed that this type of communication serves an essential therapeutic function as well.

'Dream analysis' developed in the context of the method of free association, and constituted, in Freud's (1953b) view, a 'royal road to the unconscious.' Freud's discovery of primary process thinking derived from his method of dream analysis. By now, psychoanalytic thinking has evolved into the view that there are many 'royal roads' to the unconscious. The analysis of character defenses, for example, or of particular transference complications, may be equally important avenues of entry into the patient's unconscious mind.

The technique of dream analysis consists, in essence, in asking the patient to free associate to elements of the 'manifest content' of the dream, in order to arrive at its 'latent' content, the unconscious wish defended against and distorted by the unconscious defensive mechanisms that constitute the 'dream work,' and have transformed the latent content into the manifest dream. The latent content is revealed with the help of the simultaneous analysis of the way in which the dream is being communicated to the analyst, the 'day residuals' that may have triggered the dream, the unconscious conflicts revealed in it, and the dominant transference dispositions in the context of which the dream evolved. Dreams especially to Gustave Jung, a contemporary of Freud, also provide some residual, universal symbolic meanings that may facilitate the total understanding of the latent content.

'The analysis of character' may be the single most important element of the psychoanalytic method in bringing about fundamental characterological change. Character analysis is facilitated by the patient's use of reaction formations, that is, his defensively motivated character traits, as transference resistances. Thus, the activation of defensive behaviors in the transference, reflecting the patient's characterological patterns in all interpersonal interactions, facilitates both the analysis of the underlying unconscious conflicts, and in the process, the resolution of pathological character patterns. The result is an increase in the patient's autonomy, flexibility, and capacity for adaptation. As modern research into temperament, that is, the genetically inherited components of personality, evolves, there will certainly be an influence on how psychoanalysts understand and address character during treatment.

The overall objective of psychoanalytic treatment is not only the resolution of symptoms and pathological behavior patterns or characteristics, but fundamental, structural change, that is, the expansion and enrichment of ego functions as the consequence of resolution of unconscious conflict and the integration of previously repressed and dynamically active id and superego pressures into ego potentialities. Such change is reflected in the increasing capacity for both adaptation to, and autonomy from, psychosocial demands and expectations, and an increased capacity for gratifying and successful functioning in love and work.

Treatment Results: Research on Outcome

The Menninger Psychotherapy Research Project, a naturalistic study comparing psychoanalysis, psychoanalytic psychotherapy, and supportive psychotherapy, showed psychoanalysis to be the most effective of these approaches with patients presenting relatively good ego strength, while patients with severe ego weakness – what nowadays would be described as presenting severe personality disorders or borderline personality organization – improved most with psychoanalytic psychotherapy (Kernberg et al., 1972). This research also showed how important supportive elements were throughout all modalities of treatment (Wallerstein, 1986). A comprehensive review of outcome studies on psychoanalytic psychotherapy and psychoanalysis by Bachrach and collaborators (Bachrach et al., 1985) concluded that the improvement rates are in the 60–90% range, but it also pointed to limitations and problems in the methodology utilized.

Recently, studies regarding the treatment process and outcome of psychoanalysis and psychoanalytic psychotherapy have become more precise in defining the specific treatment variables of psychotherapeutic and psychoanalytic treatments, and several systematic studies on psychoanalytic psychotherapies and psychoanalysis are in progress (Fonagy, 1998). A recent study by the Stockholm Outcome of Psychoanalysis and Psychotherapy Project (STOPPP) has found, on the basis of a relatively large patient population, that psychoanalytic treatment, in comparison with psychoanalytic psychotherapy, obtained a significantly higher degree of long range symptomatic improvement (Sandell et al., 1997b).

Modern research into various forms of psychotherapy has been slow to develop, but has expanded dramatically in recent years. While the individual case study was considered the gold standard of psychoanalytic research for much of the twentieth century, which actually impeded use of modern research techniques in psychoanalysis, there is an increasing recognition that larger sample size studies using modern psychotherapy research approaches are necessary to validate the effectiveness of psychoanalysis itself as a treatment. The emerging body of research in both psychoanalytic psychotherapies and cognitive behavioral psychotherapies, treatments which emerged from psychoanalysis itself, does suggest, however, that treatments based on the principles elucidated in the discussion in this article are at least as effective as other forms of psychotherapy, and, in certain psychiatric conditions, such as depression, are at least effective, if not more so, than medications. Finally, all psychiatric treatments appear to be more effective when informed by concepts regarding the nature of and importance of the therapeutic alliance which originated with psychoanalysis.

Psychoanalytic theories continue to evolve, as do the treatment indications, and the techniques utilized. There is a vast-literature which provides more depth of review than is possible here. An example of another well referenced brief review was done by Haggarty and colleagues (Haggard, 2008).

Psychodynamic Therapy: Short-Term

Abstract

Short-term dynamic therapy (STDP) comprises a group of interventions based on psychoanalytic principles that have been adapted for use in treatments of limited duration. The prototypic definition of STPD includes the following aspects: the theory of psychopathology explaining the disorder and treatment techniques employed (e.g., clarification, interpretation, and confrontation) that are psychoanalytic in origin; the selection of patients on the basis of their ability to withstand intensive psychotherapy; treatment that is time-limited and focused on a specific issue or conflict; and treatment aimed to provide symptom relief or limited personality or character change. STPD was developed by a subgroup of psychoanalysts who were trying to increase the efficiency of psychodynamic therapy, to bring its power to short-term settings (seeing patients once or twice a week, sitting up), and therefore to make the treatment available to a potentially broader group of patients. Subsequent changes in health care financing and reimbursement and increased awareness of data supporting its efficacy have driven increased interest in STDP.

Modern STDP proponents have developed treatment manuals detailing their specific therapeutic techniques and these manuals have not only aided in the training of the next generation of clinicians, but they have also been used in efficacy studies of STPD to ensure that therapists follow treatment guidelines. Meta-analytic reviews of STPD suggest that it is as effective as other therapies for a range of disorders and more effective than control conditions.

Short-term psychodynamic therapy (STPD) denotes a 'family' of psychotherapeutic interventions with a common theory and technique based on psychoanalytic ideas and approaches and adapted for use in short-term settings. These treatments have also been referred to as time-limited dynamic psychotherapy, brief dynamic psychotherapy, or psychodynamic psychotherapy (Crits-Christoph and Barber, 1991; Messer and Warren, 1995). The number of psychotherapies classified as 'short-term dynamic' has increased remarkably in recent decades. As these numbers continue to grow, along with new theory and attempts at integration across psychotherapies, the definition of what constitutes short-term psychodynamic treatment has become blurred.

We employ the following prototypical definition of STPD based on criteria from various authors, including Crits-Christoph et al. (1991):

1. The theory of psychopathology explaining the cause and maintenance of the psychological disorder has a psychoanalytic basis. This may include Freudian, neo-Freudian, interpersonal object relations, self-psychology, mentalization-based, attachment-based, and relational theories. Central constructs include unconscious motivation, internal conflict, a developmental perspective including the formative role of early years on character, the importance of early relationships, the tendency to repeat conflicts, the pervasiveness of transference, and the use of characteristic defenses.
2. The main treatment techniques employed by the STPD therapist include those described in the psychoanalytic literature, such as open-ended exploration; attention to the therapeutic relationship; making clarifications, interpretations, and confrontations; and noting transference and countertransference. The therapist's theoretical convictions will shape his or her approach to each of these basic treatment techniques, for example, an STPD practitioner with a relational background would be more likely to focus on the present moment and the therapist's inner experience even in the short-term setting. Although the therapist maintains a psychoanalytic stance in the sense of neutrality and abstinence, the short-term model promotes a more active exchange between therapist and patient than would be typical in traditional long-term psychodynamic therapy or psychoanalysis. They would also tend to not emphasize free association.
3. The length of treatment is planned, often predetermined, and always time-limited. It usually lasts from 12 to 40 sessions depending on the patient's problem.
4. Patients are typically screened for STPD to try to select those more likely to respond. In the literature, the following characteristics have been mentioned as predictive of a good outcome: psychological mindedness, recognition that present problems are at least partly of a psychological nature, willingness to change, the existence in the present or past of at least one good quality interpersonal relationship, the ability to circumscribe present complaints to one symptom, the capacity to interact flexibly with the interviewer, neurotic and not psychotic defenses, adequate reality testing, and the ability to tolerate frustration and ambivalence.
5. A focus of treatment is maintained and issues not related to the focal point or central conflict are regarded as lower priority. In general, the focus of treatment is developed collaboratively before therapy starts or immediately following the initiation of therapy. The therapist actively works to maintain the treatment focus on the agreed upon core problem.
6. STPD is intended to alleviate specific symptoms and provide limited personality or character change. This is in

contrast to psychoanalysis and long-term psychodynamic therapy where the goal is typically pervasive character change.

7. In general, the use of advice and homework, often practiced in behavioral and cognitive psychotherapies, is not recommended.

Because most forms of STPD do not fulfill all of the aforementioned requirements, these criteria cannot be considered necessary. As components of a prototypic definition, the more criteria a therapy meets, the more consistent it is with STPD.

Historical Background

Modern psychotherapy can be traced to Sigmund Freud's work beginning in the late nineteenth century. Freud developed a method to investigate the mind that ultimately evolved into the therapeutic intervention known as psychoanalysis. In traditional psychoanalysis, the analyst attempts to bring repressed unconscious conflicts to the patient's awareness. By gaining understanding ('insight') into the unconscious aspects of their problems, patients have the opportunity to work them through and subsequently master their difficulties. Although Freud originally worked with patients for a small number of sessions, the duration of psychoanalytic treatment increased into a multiyear process. Gradually, psychodynamic psychotherapy, also referred to as psychoanalytic psychotherapy, emerged as a modified application of psychoanalytic principles and therapeutic techniques.

Long-term psychodynamic therapists tend to be relatively quiet, wait for patients to free associate, and observe how the patient–therapist relationship (or transference) develops. This approach, quite consistent with psychoanalysis, still differs from traditional psychoanalysis in significant ways. While psychoanalytic patients lie on the couch 4–5 times a week, long-term psychodynamic patients sit face-to-face with the therapist once or twice a week for an extended period of time.

Short-term dynamic psychotherapists have modified the traditional principles even further. Work in this area originated with Ferenczi (1950), Rank (1936), and Alexander and French (1946), who recommended the maintenance of an active stance in therapy to hasten the exploration of unconscious material. In spite of their description of a seemingly useful treatment, many psychodynamic clinicians continued to view STPD as inferior to psychoanalysis or long-term psychodynamic therapy. It was not until Malan (1976), Mann (1973), Sifneos (1979), and Davanloo (1980) that STPD was deemed a valuable treatment option. The works of these authors are regarded as the four 'traditional' approaches to STDP (Crits-Christoph et al., 1991). They established a clear theoretical framework and sets of techniques to make focused and brief psychodynamic treatment possible. Malan's emphasis on the importance of careful patient selection through the screening of inappropriate referrals and trial interpretations attuned therapists to the fact that STPD can be effective for a subset of the patient population. Malan and Sifneos were also among the first to stress the significance of defining and maintaining a therapeutic focus as a central aspect of STPD technique.

Malan (1976) expressed what he saw as the essential psychodynamic theory in his description of two triangles. The first triangle is the 'triangle of conflict.' Its apices correspond to 'defense,' 'anxiety,' and 'underlying feeling or impulse.' The second triangle is the 'triangle of person' and refers to 'relationships with current figures,' 'relationship with the therapist (representing transference),' and 'relationships with important figures from the past' (e.g., parents). According to Malan, the therapist's task is to expose the underlying feelings and impulses that the patient has been protecting via defense mechanisms and to elucidate the role of the defenses in reducing the anxiety that the feelings create. He posited that the patient's hidden feelings were originally experienced in important early relationships and since then have frequently recurred with other significant figures in the patient's life, including the therapist. During therapy, the patient must understand the hidden impulses underlying each of the relationships described in the triangle of person. Typically, insight into a current relationship (either with a significant other or the therapist) is achieved first and is then related back to the parental figures.

Davanloo's intensive short-term dynamic psychotherapy (ISTDP) went further and supposedly broadened the range of patients who could be helped with STDP. He emphasized accessing the unconscious emotional content that is at the core of a number of psychoneurotic or borderline disorders by following a series of well-defined phases of clinical processes and interventions (Abbass and Town, 2013). The ISTDP therapist encourages the patient to engage with the emotional content of his or her past experiences (i.e., *pressure*), which in turn activates unconscious anxiety and related defenses. Under *pressure*, the patient experiences *complex transference feelings* and attempts to resist them. As the therapist actively and tenaciously clarifies the resistance and challenges the mobilized defenses, the patient eventually experiences *transference feelings* through somatic pathways, which in turn alleviates unconscious anxiety and eliminates resistance. Thus, the unconscious becomes *unlocked*, and the patient and therapist are able to collaboratively review unresolved, unconscious emotions, especially those related to attachment trauma. As needed, the process is repeated to unlock more unconscious material and work through it collaboratively (Abbass and Town, 2013).

Toward the end of twentieth century, a new generation of short-term psychodynamic therapists appeared on the clinical scene. Among the most important are Luborsky (1984), Horowitz et al. (1984), Strupp and Binder (1984), and Weiss et al. (1986). This new group can be distinguished from previous therapists by their interest in the empirical status of their treatments. Perhaps resulting from their interest in research, this new generation of therapists has written detailed descriptions of their clinical approaches that are very helpful for training and monitoring clinicians in these techniques. In fact, many of their books are considered treatment manuals and have been used in empirical research addressing the efficacy of these therapeutic methods. For example, Barber et al. (2012) recently tested the efficacy of

supportive expressive therapy (SET), (Luborsky, 1984) for depression and Leichsenring et al. (2013) tested its efficacy for social anxiety disorder. SET is an STDP model that has a relatively large amount of research regarding both its central concepts and its efficacy.

Recent developments include protocolized psychodynamic treatments for specific diagnoses. For example, Milrod et al. (1997) developed a treatment manual for the psychodynamic treatment of panic in 24 sessions. Weissman et al. (2007) developed interpersonal therapy for the treatment of depression. While there is some debate about the extent to which interpersonal therapy relies on psychodynamic principles and techniques, it is consistent with many of the criteria mentioned above and was developed to represent a time-limited researchable form of dynamic therapy. The theory behind this treatment holds that depression is caused by a loss or role transition, which the patient must understand using a relationship-focused model; and emphasis is placed on developing a current adaptation that will meet the present emotional needs of the patient and also provide a better solution to the conflicts stirred up by the loss. Emotional exploration of the loss in a time-limited treatment setting is a key element of the technique.

More recently, there has been an increased interest in the concept of mentalization. According to Bateman and Fonagy (2006), mentalization is the process by which we implicitly and explicitly interpret the actions of ourselves and others as meaningful on the basis of intentional mental states. Problems in mentalization are thought to be the basis for a variety of psychiatric problems, chiefly borderline personality disorder. Mentalization-based therapy (MBT) was developed for this patient population to increase mentalization capacity and thereby improve affect regulation and interpersonal relationships. This treatment, which is just beginning to be investigated outside of Borderline Personality Disorder, is delivered in a variety of formats, some of which are consistent with our prototypic definition of STPD. MBT is now being studied for the treatment of depression (Lemma et al., 2011).

The short-term psychodynamic treatments most recently developed, such as panic-focused psychodynamic therapy and MBT, were individually designed to focus on a particular diagnostic problem. Summers and Barber (2009), in their attempt to synthesize contemporary psychodynamic therapy theory and technique, describe an umbrella of treatments, all of which are psychodynamic and share similar underlying principles. They survey the evidence base for psychodynamic therapy efficacy and propose a model emphasizing the conceptual and technical building blocks of the therapy. These building blocks are: therapeutic alliance development, diagnosis of a core psychodynamic problem, psychodynamic formulation, goal setting, new narrative strategies for facilitating change, and the role of positive emotion. An important element of their work is the careful delineation of six core psychodynamic problems – depression, obsessionality, fear of abandonment, low self-esteem, panic, anxiety and trauma – which provide the clinician a roadmap for anticipating and working with patients with these problems; and the relevant modifications of psychodynamic technique are regarded as most helpful. The model is used in both shorter term and longer term settings.

Another noteworthy recent development in STDP is an alliance-focused, manualized treatment model, referred to as Brief relational therapy (BRT; Safran and Muran, 2000), which was derived from research on ruptures in the therapeutic alliance, and incorporates principles from contemporary psychoanalysis (e.g., multiple selves, intersubjective negotiation) and from research on affect regulation and interpersonal process. BRT involves an intensive 'here-and-now' exploration of patient–therapist interactions and intersubjectivity, following the technical principle of meta-communication (i.e., communication about the communication process) with the ultimate aim of expanding 'awareness in relation' – as opposed to resolving core conflicts or correcting pathogenic beliefs. It has been applied as a 30-session protocol to personality-disordered patients with promising empirical support (Muran et al., 2005).

Efficacy of STPD

During the 1980s, researchers began to explore the efficacy of STPD relative to other psychotherapies. Representing the trend toward methodological rigor that prevailed throughout the 1980s and 1990s, manualized STPDs have slowly been incorporated into research studies to provide the standardization of treatment that is needed for the studies to be credible (*see* Psychological Treatment, Effectiveness of). Leichsenring et al. (2004), published one of the most important meta-analysis of STPD in a prestigious journal and showed that when one looked at high-quality studies of STPD ($n = 14$), STPD is significantly more effective than control conditions and not different from alternate treatment. Because the meta-analysis published by Leichsenring et al. did not differentiate among disorders and needed to be updated, several meta-analyses have been conducted since. Most recently, Barber et al. (2013) examined the efficacy of STPD for specific disorders focusing on depressive, anxiety, and personality disorders. They conducted separate meta-analyses involving the comparisons of STPD with control conditions and STPD with individual treatments for each family of disorders. They reported that STPD was significantly more effective than control conditions for depression (5 studies, medium effect size 0.57) and that STPD did not differ from alternative active treatments (12 studies, nonsignificant finding $g = -0.09$); those results were maintained at short-term follow up (7 studies, nonsignificant difference, $g = 0.03$) and at long-term follow up (6 studies, nonsignificant difference, $g = -0.12$). Barber et al. (2013) reported that STPD for patients with anxiety disorders was significantly more effective than control conditions (3 studies, large effect size 0.78) and that STPD did not differ from alternative active treatments (8 studies, nonsignificant finding $g = 0.08$). These results were maintained at short-term follow up (6 studies, nonsignificant difference, $g = -0.16$) and at long-term follow up (6 studies, nonsignificant difference, $g = -0.15$). Patients with personality disorders were more effectively treated with STPD compared to control conditions (7 studies, medium effect size, $g = 0.60$) and STPD did not differ from alternative active treatments (7 studies, nonsignificant finding $g = -0.16$); these results were maintained at short-term follow-up (5 studies, nonsignificant difference, $g = -0.06$).

In a recent development, meta-analyses have been conducted for specific forms of STDP. Abbass et al. (2012) concluded that ISTDP produced large effect sizes as compared to control conditions, and that ISTDP patients maintained gains in general psychopathology and interpersonal functioning at follow up. Most importantly, not only is ISTDP highly effective, but it has also been shown to be a highly cost-effective treatment, resulting in significant reduction in a variety of health care costs as patients maintain their treatment gains and become more functional (Town et al., 2013).

In summary, STDP is more effective than control conditions for a variety of disorders and does not differ from alternative treatments (including cognitive behavior therapy) for a range of disorders. There is some evidence that therapy adding STDP to medication is more effective than medication alone ($g = 0.47$) (Barber et al., 2013).

Process Research

Most of the research associated with STPD involves the study of the therapeutic process underlying therapy in general and STPD in particular. There is a rich literature and it is impossible to give it justice in a brief essay. In their review of the literature on the therapeutic alliance and the other mechanisms of change, Barber et al. (2013) reported that the alliance was associated with outcome (studies, $r = 0.2$). Strong findings in the literature on process research indicate that both nonspecific therapeutic factors (such as a positive therapeutic alliance) and specific therapeutic factors (such as accurate interpretations of the patient's core interpersonal conflicts, change in the maturity of psychological defense mechanisms, and increased self-understanding) are associated with good therapeutic outcome (Barber et al., 2013).

The Future of STPD

Short-term dynamic therapy has flourished in the last 30 years because of cultural change in beliefs about mental health treatment, increased financial pressure to shorten treatment, increased patient interest in effective and quicker treatment, and the social demand for greater transparency. There are burgeoning new forms of STPD as well as increased utilization. Some would say there are more therapies than can be adequately studied. There is little reason to believe that the multiple causes influencing the trend toward brief treatments, including STPD, will reverse any time in the coming decades.

We anticipate at least four lines of change in the field of psychotherapy relevant to STDP in the coming decades: an increased trend toward integration, more interest in defining those subpopulations best helped by different treatment packages and interventions, more emphasis on monitoring outcome, and more need for specific training in diagnostic-specific treatment.

The Trend toward Integration

We are witnessing the increasing use of techniques that are developed for one treatment and are rapidly adapted for other treatments. For example, accelerated experiential dynamic psychotherapy borrows from experiential therapy and targets the deepening of affective experience as the mechanism of therapeutic change (Fosha, 2000; Fosha and Slowiaczek, 1997), while maintaining a relational and psychodynamic therapeutic frame. Most dynamic therapists today pay attention to faulty thinking and dysfunctional attribution, importing traditional cognitive techniques. Similarly, many cognitive behavioral therapists speak about working on the therapeutic relationship and dealing actively with transferential issues. As STPD is becoming increasingly more integrative and eclectic, examining the efficacy of the actual treatments used in clinical settings and defining a given treatment delivered by a specific clinician as STPD is becoming increasingly difficult. Modern psychotherapy including STPD, must constantly evolve to fit with the fast-paced nature and current trends of the modern world. Thus, it is likely that the future practice of STPD will include more components from other psychotherapies.

A Trend toward Individualized Psychotherapies

One conclusion from the research literature on medicine (and especially on psychotherapy outcomes) is that there is no one therapy that works for everyone with a particular diagnosis. More and more, clinicians and researchers agree that a range of treatments are needed to optimize outcome for patients with a specific diagnosis. For example, Barber et al. (2012) recently showed that STPD was not differentially effective from medication or pill placebo for all patients; but it was more effective than the latter for minority male patients.

A Greater Emphasis on Monitoring Patient Outcomes

With the increasing requirement for accountability and the monitoring of patient outcomes, there is likely to be more pressure on clinicians to use evidence-based interventions and for those interventions to lead to a good outcome for a specific patient. There is interesting evidence suggesting that when patients' outcomes are communicated to therapists, these outcomes tend to improve over time.

A Great Need for Specific Training in Diagnostic-Specific Treatment

As the evidence for STDP strengthens, it will be necessary to train more clinicians. This is especially important for the treatment of specific DSM patient populations.

Abstract

Psychohistory developed primarily in America beginning in the 1950s. Two main tenets distinguish its approach to the human past. One is that history is strictly what people did, with its supposedly impersonal developments reducing to so much human performance. The other is that the determinants of human conduct whether individual or collective are largely unconscious. In this, as in its abiding concern with childhood and pathology, psychohistory shows its derivation from psychoanalysis. But it has outgrown its initial dependence on clinical theory to develop an agenda of its own stressing behavior in and by groups. It has also originated concepts later adopted in clinical theory, such as traumatic reliving. This key concept also instances a general trend in the field: mental mechanisms are replacing unconscious motivations as explanatory devices. The methodological problems of sounding groups and verifying findings are daunting. With its rules of evidence tightening under outside criticism, the scholarly field is depopulating. At the same time, the need for psychohistorical insight is being felt increasingly in other walks of history, as for instance in historical demography to explain how populations regulate their total numbers. This growing felt need assures psychohistory of renewal as a discipline in its own right.

Its Meaning

The term *psychohistory* (originally written *psycho-history*) emerged in America in the 1950s to designate historical writings utilizing psychology, for the most part depth psychology, as their primary frame of reference or mode of explanation. Two of its tenets in particular distinguish psychohistory sharply from other systematic approaches to the human past. The first of the two, which is rarely spelled out even in methodological writings, is that the facts of human history consist entirely of what people did whether spontaneously or under pressure of circumstances. To the psychohistorian, an intellectual revolution thus signifies thinkers changing their minds; a decline in fertility translates as women bearing fewer children; urbanization conveys people living increasingly in cities. Other historians may agree that even such seemingly impersonal historic developments all come down to human doings, yet whenever other historians narrate or explain developments of the sort they tend in the first instance to see belief systems or birth rates or urban:rural ratios changing rather than people thinking or acting differently. The other highly distinctive tenet of psychohistory is, by contrast, fully and even emphatically explicit in the psychohistorical literature: that the determinants of human conduct, whether individual or collective, are largely unconscious. Historians of other schools will often freely acknowledge deeply subjective causation of historic human behavior only to shy away from it in their own research as too dauntingly difficult to reconstruct, let alone demonstrate. To the psychohistorian, however, whatever the difficulties involved, there is simply no other way for history to be understood (*see* History, Theories and Methods).

Its Development

Psychohistory originated as applied psychoanalysis, with Freud and his disciples drawing on their clinical findings now and again to illuminate historical facts. At first, those clinical findings bore heavily on the patterns and pitfalls of individual emotional development, with a strong emphasis on pregenital sexuality as it emerges in childhood bit by bit and then undergoes repression even while continuing to inform emotional life. Accordingly, the earliest applications of psychoanalysis to history – including those by Freud himself, who long set the standard for his followers – were biographic and focused on the infantile concerns latent in the words and deeds of eminent or paradigmatic historic figures (*see* Biography: Historical). A landmark work in this category was psychoanalyst Erik H. Erikson's *Young Man Luther* of 1958, which argued that Luther's bold quest for spiritual autonomy was that of his whole age writ large (*see* Erikson, Erik Homburger (1902–94)). Unlike biography in relation to historiography as a whole, psychobiography remains to this day the basic as well as the leading form of psychohistory. At the same time, it was as quick as psychoanalysis itself to move beyond its initial Freudian orthodoxy (*see* Freud, Sigmund (1856–1939)). Post-Freudian concepts utilized in psychobiography when this is practiced as applied psychoanalysis have notably included C. G. Jung's 'individuation,' Alfred Adler's 'inferiority complex,' Erik H. Erikson's 'identity crisis,' Heinz Kohut's 'narcissistic rage,' and Jacques Lacan's 'language of the id.'

Psychohistory long continued to show its derivation from psychoanalysis even where it broadened its scope beyond psychobiography. As late as the 1970s psychohistorians who explored social groups, whole cultures, or long-range collective developments, did so as a rule only in terms of the individual psychodynamics thought to have determined them, tracing their salient characteristics to formative experiences widely shared by the individuals involved, and most often to pathogenic childrearing practices on the order of abrupt weaning or intrusive parenting. Correspondingly, the preferred subjects under the head of group behavior were instances of social pathology such as witchcraft, or of political pathology such as Nazism. The most systematic psychohistorical approach to group behavior to emerge on these individualistic premises is prosopography duly slanted: the profiling of the likes of saints

or witches or Nazis in terms of variables of psychoanalytical significance in their individual family histories – ages of parents and siblings, for instance, or again early parent or sibling losses (*see* Prosopography (Collective Biography)).

A prominent early alternative to the individual personality as the basic unit even of large-scale, broadgaged psychohistorical accounts or analyses was the study of a mass leader whose following interacted with him like a single composite being. Freud himself pioneered this departure from the classic individualistic model that underlay his own science of psychoanalysis. In his *Group Psychology and the Analysis of the Ego* (*Massenpsychologie und Ichanalyse*) of 1922 he treated mass phenomena for the most part as simultaneous, parallel regression by individuals, but in a couple of highly suggestive passages he speculated on human consciousness as originally shared by a Darwinian primal horde from which a leader eventually emerged with a mind and will of his own; such shared group consciousness, he considered, might revive at critical historic junctures under the spell of a charismatic leader who threw back to that aboriginal tribal chief. Freud (1939) worked this speculative construction into a highly imaginative reading of the Moses story, with Moses reincarnating the tribal father supposedly slain and later exalted by his sons acting in concert. Given the very nature of this concept of group consciousness as a reversion to a tribal leader and following, subsequent psychohistorical treatments of leader and led have mostly dealt with political collectivities such as Lincoln's or Nixon's America, or again William II's and especially Hitler's Germany.

On the Freudian model of group process, then, group identity constitutes a regressive throwback to an original shared consciousness in the face of a strong leader. But a rival conception of shared mental life, one that makes it out as permanent and leaderless, came into psychohistory independently. Its *locus classicus* lies outside of psychohistory: in the 'collective consciousness' (*conscience collective*) that Emile Durkheim in his *Suicide* of 1897 inferred from the patterned regularity of suicide rates over and beyond the particular subjective causation of each individual suicide. An early specimen of such a leaderless group model in psychohistory was Caroline E. Playne's *The Neuroses of the Nations* of 1925, which owed nothing to psychoanalysis and indeed wholly ignored it. When William L. Langer, in a resounding presidential address to the American Historical Association in 1957, called the mastery and use of depth psychology the historian's 'next assignment,' he expressly meant its application to leaderless group phenomena, which he exemplified by the epidemic of religious and cultural pathology that followed in the wake of the Black Death of 1348. (Oddly, Langer made no reference to a pioneering work in this mold just then published by his Harvard University colleague Walter Abell (1957) about how the waxing and waning insecurities of medieval European life were projected into Europe's public art of the time.) By the 1970s the dynamics of 'group process,' as it came to be called, topped the psychohistorical agenda, with collective fantasy as its privileged medium of analysis. An exemplary early product of this approach to group process was Paul Monaco's (1976) work, which teased the deep-lying national anxieties of France and Germany in the 1920s out of the recurrent motifs and techniques of each country's most popular movies of those years. Another choice area, still under exploited, for ferreting out the unconscious underpinnings of group activity is historical demography (*see* Historical Demography), especially the adjustments of aggregate birth rates to the felt needs of a population with regard to its overall numbers.

As the term 'group process' itself implies, explanation in psychohistory gradually has shifted from unconscious motives and meanings to unconscious mechanisms governing thought and conduct, while conscious purposes have been even more marginalized in the process. This shift reflects the continuing self-distancing of psychohistory from its parent discipline of psychoanalysis, focused as the latter is on latent impulses originating in childhood. Nowhere is this shift more evident than in the concept of traumatic reliving, which matured within psychohistory well before it was taken up in psychoanalysis. Psychoanalysis had first confronted adult psychic trauma during World War One in the form of battle shock for which, as for other emotional ailments, it sought a childhood referent that in this case was not forthcoming. Comparative psychobiography established two patterned, alternative reactions to emotional trauma: either a continual recall accompanied by the full, tormenting original affect, or a repression of the traumatic affect, and sometimes even of the traumatic memory itself, followed by a contrived, controlled, disguised reexperience or reliving of the trauma to the apparent end, never attained, of mastering the attendant affect that could not be mastered at the time of the experience itself. These same mechanisms have subsequently been shown to operate as well on the collective level in instances of group trauma, and to operate independently of the widely varying reactions of the individuals composing the traumatized group. Precursively, William L. Langer in handing out his 'next assignment' conceived of the after effects of the Black Death, notably its morbid reenactments such as the Dance of Death, as just such a case of group traumatic reliving.

Its Problematic

Psychohistorical research is uniquely demanding of its practitioners because of its concern with subjective phenomena that are rarely if ever directly recorded. To understand a piece of the human past psychohistorically, researchers must first master the relevant facts at least as thoroughly as the practitioners of any other mode of inquiry. But much more, they must become immersed in those facts, make them vicariously their own, and feel out their inner determinants by dint of this imaginative identification with their original experience. The method is strikingly like the one promoted by Henri Bergson under the name of 'intuition': to study a subject intellectually from the outside until one enters into it subjectively through a core insight around which everything known about it will then fall into place. Such intimate, personal self-projection into a historic subject is trebly problematic. For one thing, it presupposes a basic equivalence of mental and emotional constitution as between researchers and their human subjects, however remote those subjects may be from them historically, and even if they are groups rather than individuals like

themselves. For another, researchers' identification with their subject must be thorough-going, yet unless they can also sustain some critical awareness outside of that identification the insights gained through it will be lost. And for a third, pieces of the researchers' own mental underworld may slip unnoticed into their reading of a subject. This danger, often called 'countertransference' by loose analogy with psychoanalysts projecting into their patients, is the risk most cautioned against by psychohistorians themselves. Actually, an affinity in researchers for their subject's inner experience can, on the positive side, sensitize or alert them to connections and meanings they might otherwise miss. Besides, a purely projective finding will not stand up in any case inasmuch as it will fail to fit all the evidence, let alone satisfy anyone apart from the researchers themselves.

Researchers will feel the rightness of their inner grasp of a subject when it not only pulls together all the relevant facts at their disposal, but points the way to unsuspected additional corroborative evidence. Yet the discovery of such new evidence, however suggestive, is in itself no proof that their inner grasp of their subject is universally valid. Because of the very nature of psychohistorical explanation, to validate a psychohistorical thesis takes more than just a wealth of corroborative material, even if the thesis itself is what turned up key pieces of that material. To pass muster, a psychohistorical thesis must also carry subjective conviction, beyond the researchers themselves, with others willing and able to put themselves in the subject's place in their turn and see whether the proposed unconscious source of the thought or action at issue checks out subjectively with them too.

This second, subjective criterion of verification means in brief that a psychohistorical thesis must be emotionally as well as intellectually compelling. Consequently it can rely on no pregiven theory for support. Yet however direct its appeal, its need for subjective on top of objective verification demands too much effort, not to add goodwill, ofcritics accustomed instead to merely material and logical criteria of validation. As a substitute test of validity I therefore propose that, in psychohistory as in any science, a thesis is confirmed if, first of all, the known evidence all runs its way, if moreover it could potentially be refuted by new evidence, and if finally any piece of what it purports to explain cannot very well be explained otherwise. To take a simple example of this last stipulation from my own thesis that Hitler was traumatized by his mother's iodoform poisoning during her terminal cancer treatment: why else did he put it to his generals in late 1944 that his Ardennes offensive had caught the Allies off guard because they believed he was dead already 'or at all odds am down with cancer somewhere and can't live any more or drink any more' except that deadly iodoform poisoning induces a burning thirst together with an inability to drink? (Binion, 1976, p. 143).

Its Crisis Years

As a historical school in its own right, psychohistory flourished above all in the US during the 1960s and 1970s. Even then, like all new departures, it was highly controversial, especially within the historical professions, because of its constitutive tendency to undercut all other modes of historical explanation. It has since suffered considerably from the decline of psychoanalysis, with which it is rightly associated in that the two still share at least the premise of unconscious motives and meanings. Experimental graduate programs in the field have all folded, while course offerings on college campuses have dwindled to the vanishing point. The ranks of researchers in the field are fast thinning even as the stringent standards of verification invoked for it by critics and adepts alike are discouraging prospective practitioners. Fewer psychohistorical books and articles are appearing year by year. Of the two major specialized journals, *The Psychohistory Review* ceased publication in 1998 while *The Journal of Psychohistory* has lost most of its initial circulation. Perhaps worst of all for the discipline, the consensus of outsiders is that its scholarly output is falling off qualitatively as well.

On the other hand, psychohistory has left its impress on most other kinds of historical inquiry, especially those that emerged or developed later than psychohistory itself. Biographies and even general histories now routinely incorporate psychohistorical materials and interpretations. The study of mentalities often verges on psychohistory. So does that of historic memory, especially in the concern with memory gaps or distortions that has dominated the field. Gender history and gay history, as well as the history of emotions, lean heavily on psychohistorical concepts and findings. Many a term launched in psychohistory, such as Erikson's 'identity crisis,' has become common coinage elsewhere, while the mechanism of traumatic reliving by individuals and groups alike has found its way into a broad variety of scholarly contexts, including even a quantitative history of testation in late medieval Tuscany (Cohn, 1992) (*see* Identity in Childhood and Adolescence).

The fact that psychohistory has lost much of its vitality of the 1960s and 1970s, or again that it is being put to subordinate uses by historians of other orientations, does not affect its constitutive claim to provide a privileged access to causality in history. Given this inherently persuasive claim, neither the recent loss of momentum by psychohistory as a method in its own right nor its present auxiliary status in historical research can very well be regarded as permanent.

Psycholinguistics: Overview

Brian MacWhinney, Carnegie Mellon University, Pittsburgh, PA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Psycholinguistics combines methods and theories from psychology and linguistics. It attempts to evaluate the psychological reality and underpinnings of linguistic rules and processes. It also seeks to link word and sentence processing to the deeper expressive processes of message construction and interpretation. Modern psycholinguistic theories emphasize the ways in which distinct areas of the brain interact in a dynamic incremental way to process language.

Introduction

Psycholinguistics is a field that combines methods and theories from psychology and linguistics to derive a fuller understanding of human language. From psychology, it inherits experimental methodology and a body of knowledge about processes in perception, memory, attention, learning, and problem solving. From linguistics, it derives detailed descriptions of specific languages, rigorous accounts of the shape of grammar, and ideas about the nature of human language.

The initial issue that motivated the establishment of psycholinguistics as a separate field of study was the problem of the *psychological reality* of linguistic concepts (Sapir, 1933/1968). In the 1960s, researchers wanted to know whether the various rules of Chomsky's new Transformational Generative Grammar (Chomsky, 1957) are actually used by humans. Although the results for this particular issue were largely negative, the core interest in psychological reality has continued unabated. To take a simple example of the issue, consider the claim that speakers of English can form the plurals of nouns by adding the suffix – *s*. This process allows us to form the plural *chandeliers* from *chandelier*. But do we actually use a productive rule to produce this plural or do we simply retrieve the plural *chandeliers* from our long-term memory as a unit? Psycholinguistic research shows that, in fact, both rote and rule are operative at various times in language production (Pinker, 1999).

This issue of psychological reality applies to all levels of language structure and usage, including articulatory phonetics, auditory phonetics, phonology, morphology, lexicon, syntax, semantics, and pragmatics. It applies to all of the constructs of linguistics, including rules, grammars, paradigms, trees, segments, words, and morphemes. When we hear words, do we break them up into their component phonemes or 'letters' or do we recognize them as wholes? When we listen to sentences, do we actually construct treelike representations of the types proposed by linguists or do we somehow extract meaning without building up formal structures? If we do use formal grammars to listen and speak, what is the exact shape of the grammars that we use?

Exploration of the psychological reality of linguistic structures immediately leads us to two related fields of study. The first is developmental psycholinguistics or the study of child language acquisition (Ambridge and Lieven, 2011). If we believe that adults form the plurals of nouns by adding – *s*, we need to consider how young children apply this rule to produce *cats*, but not *foots* or *tooths*. If we argue that children simply learn each form by rote, how can we account for the fact that they make errors like *feets* and the fact that they can produce the plural for a new word like *wug*, even without having been given that form explicitly?

The issue of psychological reality also leads us to consider the even more difficult issue of how rules of grammar might be processed in the brain. Addressing this question has led psycholinguists to explore issues in neurolinguistics (Stemmer and Whitaker, 2008) and cognitive neuroscience (Gazzaniga, 2000). When the field of psycholinguistics first developed in the 1950s, psychologists knew little about the detailed functioning of the human brain and were forced to treat it as a 'black box.' However, as our understanding of the functioning of the human brain grew during the 1980s and 1990s, it became clear that a precise understanding of the functioning of human language would have to make reference to neural mechanisms. The interactive approach to cognition (Rumelhart and McClelland, 1986) used artificial neural networks to model the processing of human language. Directly opposed to connectionism was Fodor's (1983) modular approach to cognition that emphasized the independence of separate cognitive modules for each level of linguistic structure. Researchers have attempted to test the contrasting predictions of the interactive and modular approaches using standard experimental methodology. However, this work has indicated that neither of the strong positions can be maintained (Simpson, 1994).

This article will examine research in six core areas of psycholinguistics: spoken word recognition, sentence comprehension, sentence production, message construction, crosslinguistic comparisons, and neurolinguistics. In addition to these core areas, psycholinguists are involved in the study of reading, conversational interaction, figurative language, text comprehension, aphasia, child language disorders, gesture, prosody, animal communication, and language evolution. However, our analysis here will focus on these six core areas.

Word Recognition

When we listen to speech, we perceive words as following each other in clear temporal succession, like the beads on a string. However, this underestimates the extent to which words are

actually being blurred together by coarticulation and assimilation. Extreme examples of this blurring occur in forms such as *supchu* for 'What is up with you?' However, even nonphrasal sequences such as 'I owe you a yo–yo' show similar blurring. Even without blurring, the job of segmenting sentences into words would be a tough one. Consider a phrase such as 'my catalog value for Mark's piece.' Within this phrase, there are fragments that match a variety of other possible words, such as *mike*, *eye*, *I*, *cat*, *at*, *cattle*, *log*, *you*, *Val*, *ark*, *arks*, *are*, and *form*. The reason why we tend not to hear these alternative forms is fairly simple. If we decided to commit ourselves to having heard the word *mike*, we would end up with the nonsensical segmentation of 'mike at a log value for Mark's piece.' At each point during sentence perception, many of these alternative words are partially active in a short list of competitors. Competitors that recognize larger segments such as 'catalog' are preferred over those that recognize smaller strings or which break up larger strings into pieces, such as 'cat a log.' If a competitor leaves an unrecognized fragment, then its own recognition is weakened. These constraints work together to guarantee a maximally satisfactory segmentation. Although segmentation is primarily driven by the competition of words for matches, it is also facilitated by stress patterns, pauses, and other prosodic patterns (McClelland et al., 2006).

Segmentation relies on word recognition, but this process is also highly dynamic. Words do not have clear and invariant forms. Consonants leave no clear and invariant imprint on the auditory stream, as they are heavily blended into vowels. Because of differences in their vocal tracts, men and women produce vowels in radically different ways. Dialect differences and variations in speech level add further variability to word forms. Again, the solution to this problem involves lexical competition. For example, the sound corresponding to word like *deep* will activate a neighborhood of similar words, such as *deal*, *dean*, *peep*, or *keep*. Within this domain of rhyming forms, competition is particularly keen between words that share the same initial segments, such as *deep*, *deal*, *dean*, and *deed*. The ability of a word to dominate in this competition is a function of the strength of its match to the features of the input (Dahan et al., 2001). Apart from influences coming from a word's sound, there can also be influences from meaning. For example, hearing the word *doctor* will prime the recognition in both listening and reading of the word *nurse* (Balota, 1994).

These competitive models can be given a specific neuronal instantiation in terms of a neural network model based on self-organizing feature maps (Li et al., 2007). In these models, an unorganized, but interconnected, flat sheet of simulated neural tissue is trained to recognize a set of input words. As learning progresses, words that share features move to adjacent areas in the feature map. In our example, the words *deep*, *deal*, *dean*, and *deed* would occupy a small neighborhood on the larger map. The network operates in a winner-take-all fashion so that, when deep starts to receive the highest level of activation, it will inhibit the activation of the competitors through a series of lateral connections. Like actual cortical tissue, these maps use spatial position to represent featural structure, and they rely on lateral inhibition to sharpen the outcome of a competition.

Sentence Comprehension

In the 1960s, psycholinguists thought that the process of word recognition completely preceded the process of sentence comprehension. The idea was that we must first identify all the words in a sentence before we could feed these words to a comprehension mechanism that decided what it all meant. Much of what we have learned about language processing over the last 50 years involves the construction of a detailed rejection of this early vision. As we study how auditory processing, word recognition, and sentence comprehension operate in real time, we have come to see that language processing is both *interactive* and *incremental*.

Incrementalism

In the late 1970s, Marslen-Wilson (1975) and others showed processing keeps up with word recognition in a fully incremental or online fashion. Both word recognition and sentence comprehension attempt to keep up with speech exactly as it comes in, although sometimes there is a slight lag, particularly for sentence comprehension. You might notice this lag if you find that you are trying to read a newspaper while someone is talking to you. You hear their words, but you may not be processing exactly what they say. If someone then asks you whether you have been listening, you may be able to repeat the last seven or eight words they said, but in fact you were not really understanding the message. Rather, you were squirreling away the words in a superficial form in your short-term memory (Botvinick and Plaut, 2006), hoping not to have to actually do the work of fully comprehending the message.

Apart from some such marginal cases of short-term buffering, we process incoming material incrementally, both lexically and conceptually. Take as an example the sentence, 'The boy chased the baboon into the bedroom.' As soon as we hear *the* and *boy*, we immediately begin to relate them to each other. We then relate this unit to the following verb *chased*. Milliseconds after hearing *chased*, we begin to construct an interpretation of the activity in which there is a boy doing some chasing. By the time we hear *baboon*, we can begin to sketch out the figure that the boy is chasing. We do not need to wait until we have heard all the words in the sentence to begin to extract these meanings. In this sense, sentence processing is both interactive and incremental – we tend to make decisions about material as soon as it comes in, hoping that the decisions that we make will not be reversed. Although processing is incremental, it only builds as much structure as it needs in order to keep words related. The real job of comprehension is delayed until more of the message is heard.

Garden Pathing

There are times when the initial decisions that we have made take us down the garden path. A classic example of garden-path processing occurs with sentences such as 'The communist farmers hated died.' It often takes the listener awhile to realize that it was the *communist* that died and that it was the *farmers* who hated the *communist*. Inclusion of

a relativizer to produce the form, 'The communist that farmers hated died' might have helped the listener sort this out. A somewhat different example is the sentence, 'The horse raced past the barn fell.' Here, we need to understand 'raced past the barn' as a reduced relative clause with the meaning 'The horse who was raced past the barn.' If we do this, the appearance of the final verb *fell* after *barn* no longer comes as a surprise.

Garden paths arise when a word or suffix has two meanings, one of which is very common and one of which is comparatively rare (MacDonald et al., 1994). In a sentence like 'The horse raced past the barn fell' the use of the verb 'raced' as a standard transitive verb is much more common than its use as the past participle in a reduced passive. In such cases, the strong meaning quickly dominates over the weak meaning. By the time we realize our mistake, the weak meaning is fully suppressed by the strong meaning and we have to try to comprehend the sentence from scratch. A classic garden-path example from Lashley (1951) is the sentence 'Rapid righting with his uninjured left hand saved from destruction the contents of the capsized canoe.' When this sentence is read aloud, listeners find it extremely difficult to understand the second word as *righting* rather than *writing*.

Lexical Effects

Current models of sentence processing emphasize the extent to which lexical and syntactic ambiguities of individual words trigger competing syntactic structures (MacWhinney, 1987; Trueswell and Gleitman, 2004). For example, there are two readings of the sentence 'Flying planes can be dangerous.' The planes can be either dangerous to their pilots and passengers or dangerous to onlookers down on the tarmac. Both interpretations of the participle *flying* are fairly strong. Because the two readings are of similar strength, they can compete with each other and no garden pathing arises. Another example of this type is 'He bought her pancakes,' in which *her* can be either the possessor of the pancakes or the recipient of the pancakes. Both meanings are strong and can compete with each other during sentence processing, yielding a clear ambiguity.

Sometimes lexically based expectations can be fairly complex. Consider these sentences in which the verbs *criticize* and *apologize* set up contrasting expectations:

John criticized Mary, because she hadn't delivered the paper on time.
John apologized to Mary, because he hadn't delivered the paper on time.
John criticized Mary, because he hadn't delivered the paper on time.
John apologized to Mary, because she hadn't delivered the paper on time.

Processing of the first two sentences is quick and easy, because the gender of the pronoun matches that of the expected agent. However, the processing of the second pair is more problematic because the gender of the pronoun forces the selection of an unexpected causal agent of the criticism or the apology (McDonald and MacWhinney, 1995).

Modularity

Although processing on individual linguistic levels is highly incremental, the interaction between levels is not immediate. During the first 300 ms after hearing a word, we attend primarily to its auditory shape, rather than the degree to which it fits into some grammatical context. Take as an example the sentence 'The sailors took the port at night.' Here the word *port* could refer to either the wine or the harbor. We can ask subjects to listen to sentences like this while watching a computer screen. Directly after subjects hear the word *port*, we can present one of these three words on the computer screen: *wine*, *harbor* and some control word such as *shirt*. If we do this, we will find that the recognition of both *wine* and *harbor* is facilitated in comparison to the control word *shirt*. If we change the sentence to something like 'The sailors drank the port at night,' we might expect that the context would bias the subject to respond more quickly to *wine* than to *harbor*, because one is not likely to drink a harbor. However, there is evidence that both *wine* and *harbor* are facilitated in comparison to the control word *shirt*, even when the context tends to bias the *wine* reading of *port*. This facilitation is fairly short lived and the contextually appropriate reading soon becomes dominant.

This type of result indicates that, in the first fraction of a second after hearing a word, we rely most strongly on auditory cues to guide our processing. This is not to say that context is not present or not being used as a cue. However, during the first fraction of a second, we need to focus on the actual auditory form in order to avoid any 'hallucinatory' effects of paying too much attention to context too soon in processing.

Sentence Production

There are many similarities between sentence comprehension and sentence production. In both activities, we rely heavily on the words in our lexicon to control syntactic structures. Both activities make use of the same patterns for determining grammatical structures. The most important difference is that, during sentence production, we are in full control of the meanings we wish to express. In comprehension, on the other hand, we are not in control and have to follow the ideas of others.

The production of sentences involves at least four processes (Levelt, 1989). The first process is message construction. This process takes our goals and intentions and builds up a thread of ideas to be articulated. The process of lexical access then converts these ideas in worded forms. The third process uses positional patterning to order words into phrases and clauses. The fourth process activates a series of verbal gestures through articulatory planning. As in the case of comprehension, these four stages are conducted not in serial order, but in parallel, interactively and incrementally. Even before we have finished the complete construction of the message underlying a sentence, we begin the process of articulating the utterance. Sometimes we find out in the middle of an utterance that we have either forgotten what we want to say or do not know how to say it. It is this interleaved, incremental, online quality of speech production that gives rise to the various speech errors, pauses, and

disfluencies that we often detect in our own speech and that of others.

Speech errors come in many different forms. Some involve simple slurring of a sound or retracing of a group of words. Others provide more dramatic evidence of the nature of the language planning process. Some of the most entertaining speech errors are spoonerisms, which owe their name to an English clergyman by the name of William Spooner. Instead of 'dear old queen,' Spooner produced 'queer old dean.' Instead of 'ye noble sons of toil,' he produced 'ye noble tons of soil.' Instead of 'I saw you light a fire in the back quad, in fact you wasted the whole term,' he said 'I saw you fight a liar in the back quad, in fact you tasted the whole worm.' These errors typically involve the transpositions of letters between words. Crucially, the resulting sound forms are themselves real words, such as *liar*, *queer*, and *worm*. The tendency of these errors to produce real words is known as the 'lexical bias' in speech errors and indicates the extent to which the lexicon itself acts as a filter or checker on the articulatory process.

Another illuminating group of errors is named after a character named Mrs. Malaprop in the play *The Rivals* by Sheridan. Some examples of malapropisms include *Judas Asparagus* for *Judas Iscariot*, *epitaphs* for *epithets*, or *croutons* for *coupons*. Some malapropisms arise when uneducated speakers attempt to produce unfamiliar words, but many of these errors are true slips of the tongue. In a malapropism, the two words have a similar sound, but a very different meaning. The fact that speakers end up producing words with quite the wrong meaning suggests that, at a certain point during speech planning, the output processor handles words more in terms of their phonological form than the meaning they express. It is at this point that malapropisms can occur.

When two words end up directly competing for a single slot in the output articulatory plan, the result is a lexical blend. For example, a speaker may want to describe both the flavor and the taste of some food and end up talking about its *flaste*. Or we might want to talk about someone's *spatial performance* and end up talking instead about their *perfacial performance*. These errors show the extent to which words are competing for placement into particular slots. When two words are targeting the same slot, one will usually win, but if there is no clear winner there can be a blend.

Another remarkable property of speech errors is the way in which grammatical markers seem to operate independently of the nouns and verbs to which they attach. Consider an exchange error such as 'The floods were roaded' for 'the roads were flooded.' In this error, the plural marker – *s* and the past tense marker – *ed* go to their correct positions in the output, but it is the noun and the verb that are transposed. This independent behavior of stems and their suffixes indicates that words are being composed from their grammatical pieces during sentence production and that grammatical markers contain clear specifications for their syntactic positions.

Sigmund Freud believed that slips of the tongue could provide evidence for intrusions from underlying anxieties, hostilities, and worries. From this theory, arose the notion of a 'Freudian slip.' We now know that the majority of speech errors are not of this type, although there are some that can be viewed as intrusions from the context. For example, if a speaker is discussing some activities surrounding a local barber, he might say 'He made hairlines' instead of 'He made headlines.' Even rare examples of this type of contextual influence seldom point to underlying hostilities or neuroses.

Message Construction and Perspective

The basic goal of both sentence comprehension and sentence production is the linking of spoken forms to underlying conceptual meanings. In the 1970s, psycholinguists thought of these conceptual structures in terms of links between simple sentences or propositions. These propositions represented relations that had no clear relation to the actual physical perspective of the speaker. More recently, work in philosophy, robotics, psychology, cognitive linguistics, and cognitive neuroscience has recast this view of meaning structures in terms of dynamic activities that are linked to the embodied perspective of the speaker.

Consider what occurs when a speaker relates a fable, such as the story of the Tortoise and the Hare. In this story, there are basically three perspectives, one for the tortoise, one for the hare, and one for the narrator. The narrator says, 'the hare decided to rest.' At this point, the narrator is taking the perspective of the hare and describing the hare's actions from that perspective. Next, the narrator shifts to the perspective of the tortoise and describes how he passes the sleeping hare. These various shifts and blends of perspective are important aspects of all narrative structures. However, we can see their impact everywhere in language. For example, if we want to point out that there is a dent in the side of the refrigerator, we may use the impersonal construction, 'someone knocked a dent in the refrigerator' or we may use the pseudopassive, 'the refrigerator got a dent knocked into it.' In the impersonal we are forced to point a finger at an unspecified perpetrator of the deed. In the pseudopassive, we background or deemphasize the doer of the activity, focusing instead on the result. These choices all reflect variations in perspective.

Another choice we make is between alternative perspectives on a single action. For example, we could describe a picture by saying 'the girl gave a flower to the boy.' In this case, we are taking the viewpoint or perspective of the girl and describing the activity of giving from her perspective. Alternatively, we could say, 'the boy got a flower from the girl.' In this alternative form, we view the action from the perspective of the recipient. Depending on whether we choose to view the action from the viewpoint of the giver or the receiver, we will use either the verb *give* or the verb *get*. Language is full of choices of this type and sentence production can be viewed as involving a continual competition between choices for perspectives. The selection of pronouns is determined by the need to link up referents to earlier perspectives. Shifts from the present tense to the past also reflect movements in perspective to various points in time.

Crosslinguistic Comparisons

All languages have sound segments, syllables, words, phrases, and sentences. In all languages, processing is online, incremental, and interactive. However, languages differ markedly in the particular grammatical contrasts they choose to mark and

the devices that they use to mark them. In languages like Warlpiri or Hungarian, word order is remarkably flexible. In languages like Navajo or Eskimo, a single complex word may express what English does in a seven-word sentence.

Psycholinguistic comparisons of processing in different languages (MacWhinney and Bates, 1989) use a simple common task to examine the effects of radically different structures. In one type of experiment, subjects listen to a sentence such as 'The eraser is pushed by the cat' and have to point to a picture that shows who is the actor. Consider a comparison of these sentences from English and Spanish:

The lion kisses the cow.
El león besa la vaca. (The lion kisses the cow).

A major difference between these two languages revolves around the use of variable word orders. In Spanish, it is possible to invert the word order and produce 'la vaca besa el león' while still meaning that the lion is kissing the cow. This inversion is even clearer if the particle *a* is added to marker the direct object as in these variant orderings in which the two nouns are moved into different places around the verb *besa*.

El león besa a la vaca.
A la vaca besa el león.
Besa el león a la vaca.
Besa a la vaca el león.

These differences between English and Spanish can be traced to the relative cue validities of word order and object marking in the two languages. In English, it is virtually always the case that the noun that appears before the verb is the subject of the sentence. If the verb is an active verb, the preverbal noun is almost always the actor. This means that the cue of preverbal positioning is an extremely reliable guide in English to assignment of the actor role. In Spanish, there is no such simple rule. Instead, the best cue to assignment of the actor role is the presence of the object marker particle *a*. If one of the nouns in a two-noun sentence is marked by *a*, then we know that the other noun is the agent or subject.

Other languages have still other configurations of the basic cues to sentence interpretation. For example, Hungarian makes reliable use of a single case-marking suffix on the direct object. German uses the definite article to mark case and number. The Australian language 'Walpiri' marks the subject with a variety of complex case markings. Navajo places nouns in front of the verb in terms of their relative animacy in the Navajo 'Great Chain of Being' and then uses verbal prefixes to pick out the subject. These languages and others also often rely on number agreement between the verb and the noun as a cue to the subject. English also requires subject–verb agreement, but this cue is often missing or neutralized. In languages like Italian or Arabic, subject–verb agreement marking is extremely clear and reliable.

When a monolingual speaker comes to learn a second language, the learner needs to fundamentally retune his or her sentence-processing mechanism. First, the learners need to acquire a new set of grammatical devices and markings. Second, they need to associate these new devices with the correct cue validities. Third, they need to reorganize their expectations for particular sequences of cues and forms. Initially, the learner simply transfers the cues, cue validities, and habits from the first language to processing of the second language. Over a period of time, the cue validities change smoothly, until they eventually match that of the native monolingual (MacWhinney, 2012).

Neurolinguistics

Recent advances in Cognitive Neuroscience have had a major impact on psycholinguistic research. Increasingly, researchers are asking not just when and how linguistic processes interact, but also where and how processing occurs in the brain. The bulk of this work has used the neuroimaging methods of functional magnetic resonance imaging (fMRI) and event-related potential (ERP). Other methods include diffusion tensor imaging (DTI), structural MRI, lesion studies, near-infrared spectroscopy (NIRS), mismatch negativity (MMN), and single-cell recordings during surgery. Using these various methods, researchers have begun to piece together a new vision of language processing in the brain. This new account provides important roles for many cortical and subcortical regions. Frontal areas such as the dorsal lateral prefrontal cortex (DLPFC) and the anterior cingulate cortex (ACC) are seen as playing a role in the type of attentional switching needed for perspective shifting and code switching in bilinguals (Roelofs, 2011). Midbrain structures such as the striatum and basal ganglia are implicated in the development of language fluency (Ullman, 2004). A linked system of temporal and frontal areas is involved in both auditory and articulatory processing of sounds (Hickok, 2009). Studies show that the superior temporal sulcus (STS) controls many aspects of lexical processing, although other temporal areas also have some involvement. Increasing detail from DTI and other methods (Bookheimer, 2007) has shown that inferior frontal cortex or Broca's area has multiple areas for semantic, syntactic, and phonological processing, each with detailed connections through white matter tracts to other areas. The study of articulatory control in stutterers (Howell, 2011) points to a role for between-area connectivity in producing timing errors in phonological and lexical access.

The work attempting to identify areas involving aspects of language processing has shown how difficult it is to peg a function to a single area. Instead, it is becoming clear that language processing works in terms of dynamic interactions across multifunctional areas organized into flexible neural circuits (Anderson, 2010; MacWhinney, 2009). As we begin to understand the dynamic nature of these interactions, we will be able to construct a much more accurate understanding of how language is processed in the brain.

Summary

In this article, we have examined six core issues being addressed by psycholinguists. These areas are central to the study of psycholinguistics, because they allow us to evaluate the psychological reality of linguistic formalisms. The interaction between psycholinguistics and linguistic theory has been intense, reciprocal, and dynamic. We have learned that language processing is interactive and incremental in regard to

word recognition, sentence comprehension, sentence production, and message construction. We know that crosslinguistic differences in processing are closely related to differing levels of reliability for the cues involved and the ways in which structures impose demands on verbal memory capacity. Some versions of linguistic theory have moved to adapt to some of these findings from psycholinguistics (Pollard and Sag, 1994). However, a satisfactory resolution of the core issue of the psychological reality of linguistic structures has not yet been obtained.

Abstract

Psychological anthropology is the anthropological study of people's beliefs, feelings, and motivations in cultural contexts. In the nineteenth and early twentieth centuries, questions about psychic unity and diversity were a central part of anthropology, not a separate subfield. Later, Freudian theory and the growth of the cognitive sciences inspired distinct schools within anthropology: one devoted to psychoanalytic studies of culture and personality and the other to formal models of cultural knowledge. Current research draws on variety of theories, such as relational psychology, activity theory, schema theory, neurobiology, and critical theory, creating possibilities for studies that integrate thought with feeling, mind with body, and psyche with society.

Introduction

Psychological anthropology is a subfield of anthropology devoted to the way cognition, emotion, and motivation are shaped in sociocultural settings and to the psychological factors that are important in culture learning and expression. Psychological anthropologists study topics such as narrative, identity, experience, emotion, memory, discourse, belief, conscious goals and unconscious desires, conceptual structures, gender, sexuality, trauma, mental illness, stigmatization, and psychological development in diverse social and cultural contexts.

Unlike the norm in related subfields of psychology (e.g., cultural psychology, social psychology, or cross-cultural psychology), methods in psychological anthropology are usually drawn from the anthropological tool kit, including participant observation and qualitative interviews. Formal methods or experiments may be used in addition. Psychological anthropologists are often critical of the approach sometimes seen in psychological research in which culture is considered a single variable.

Unlike other subfields of anthropology that are also concerned with cultural values, beliefs, and identities, psychological anthropologists typically employ 'person-centered' methods (LeVine, 1982), that is, ones that attend to individuals' thoughts, feelings, and motivations (Hollan, 2001).

Some major subfields of psychological anthropology include cognitive anthropology (*see* Cognitive Anthropology), psychoanalytic anthropology, psychiatric anthropology, cross-cultural studies of child development, ethnopsychology, and biocultural studies.

Intellectual Background

Investigations of personality and cognition in culturally diverse societies have been conducted by social and cultural anthropologists from at least the nineteenth century on, not as a distinctive subfield but as an outgrowth of anthropologists' central interest in human differences and universals. Early in the twentieth century, Franz Boas declared in a paper titled "Psychological problems in anthropology" that his concern was "'the influence of the society' on 'the habits of action and thought of the individual'" (quoted in Stocking, 1992: pp. 318–319). Boas described the two main branches of anthropology as 'psychological anthropology' and 'biological anthropology.' For Boas, 'psychological anthropology' included all aspects of the study of 'the mind of man' (Stocking, 1992: p. 312). Debates about human psychic unity were central to anthropological theories in the late nineteenth and early twentieth centuries regarding the origins of magical, scientific, and religious beliefs. For example, Lucien Lévy-Bruhl postulated that mystical 'pre-logical' (or a-logical) beliefs were characteristic of 'primitive' mentality (Lévy-Bruhl, 1910). By contrast, E.E. Evans-Pritchard stressed the logical reasoning that upheld Zande divination practices (Evans-Pritchard, 1976 [1937]). Such studies were considered an integral part of the investigation of culture, defined by E.B. Tylor as "that complex whole which includes knowledge, belief, art, morals, law, custom, and any other capabilities and habits acquired by man as a member of society" (Tylor, 1958[1871]: p. 1).

Freudian theory provided the impetus for a separate subfield of anthropology devoted to psyche. Freud's concerns with the shaping of personality by methods of child rearing, his posited universal libidinal and aggressive drives, and his emphasis on subconscious psychic conflict that may be indirectly reflected in individual and collective symbolic expressions had a considerable impact throughout the discipline (e.g., on Claude Lévi-Strauss, Victor Turner, and Meyer Fortes) and inspired a particular approach called 'culture and personality' studies from the 1930s to the 1960s. Culture and personality studies focused on the personality traits that are predominant in a society due to its patterns of child rearing. The prominence of a few well-known culture and personality studies obscures diversity in their methods and theories. Some practitioners emphasized cultural differences in child rearing and consequent differences in typical personality. An example is Margaret Mead's early study of adolescence in Samoa, which she described as less psychologically fraught than Western adolescence because of the freer expression of libidinal instincts (Mead, 1949[1928]). Mead also described extreme variability in sex roles in three New Guinea societies, concluding that biological sex does not determine personality traits and that "human nature is almost unbelievably

malleable" (Mead, 1963: p. 280). Other culture and personality researchers began with assumptions about universals of human personality, such as the Oedipus complex. Some, such as Ruth Benedict in *Patterns of Culture* (1934) and *The Chrysanthemum and the Sword* (1946), characterized the typical personality structure of a society on the basis of their rituals, folklore, and other aspects of public culture; others administered projective tests and reported the individual variation they found (DuBois, 1961; Wallace, 1952), or made detailed observations of children's and caretakers' behaviors (Whiting and Whiting, 1975).

Starting in the 1950s, culture and personality studies came under criticism. Questions were raised about whether child rearing has lasting personality effects or, if it does, whether it has the particular effects postulated in Freudian theory. Criticisms were made of practitioners' emphasis on shared personality types at the expense of intracultural diversity, some researchers' circular method of inferring typical personalities from the social institutions they are supposed to cause, the possible lack of cross-cultural validity of Western projective tests (or their possible lack of validity in any society), ethnocentric and sometimes prejudiced descriptions of personality types, and lack of clarity about the meaning of 'culture' and 'personality' and their relation to each other (Bock, 1988; LeVine, 1982; Wallace, 1970[1961]). In the 1960s, the term 'psychological anthropology' came to the fore instead, particularly among American anthropologists. Unlike Boas's earlier inclusive meaning, 'psychological anthropology' now referred to a subfield of anthropology open to a variety of anthropological studies of psyches.

Beginning in the mid-1950s, a different set of anthropologists began using linguistic and cognitive theories and methods to investigate cultural systems of knowledge. As noted earlier, it has been common for anthropologists to describe cultural values and beliefs. What set apart the new endeavor was its sustained focus on what people think, its use of systematic person-centered methods instead of methods that infer beliefs from public culture, and the inspiration it drew from theories of cognition in the interdisciplinary cognitive sciences. This was the beginning of the major subdivision of psychological anthropology now termed 'cognitive anthropology.' Whether or not cognitive anthropologists agreed with Ward Goodenough's definition of culture as "whatever it is one has to know or believe in order to operate in a manner acceptable to its members" (Goodenough, 1957: p. 167), which reduces culture to shared knowledge (see criticism of that definition in D'Andrade, 1995), they considered such beliefs a central part of culture that could be described using some of the methods that were being developed in other fields.

Initial proposals were inspired by Prague School linguists' descriptions of the sets of distinctive features that differentiated phonemes (meaningful sounds in a language) and linguists' extension of that approach to word meanings. To give an anthropologically relevant example, kin terms in a language can be thought of as a contrast set in which items are differentiated by the presence or absence of a small number of features, such as male/female, consanguineal (blood)/collateral relation to the speaker, generation in relation to speaker, elder than/younger than the speaker (in some languages), patrilateral/matrilateral kin (in some languages), and possibly other features. Other cultural domains, such as terms for plants, animals, and foods, were modeled as taxonomies (*a*, *b*, and *c* are types of *d*; *d*, *e*, and *f* are types of *g*, and so on). Cognitive structures of this sort reveal something about the beliefs of a group at a particular time. Studies of the meanings of terms and relations between them in a cultural domain were sometimes called ethnoscience or ethnosemantics during the 1960s and the 1970s.

While logically satisfying, there were some problems with this approach to the study of people's cultural knowledge. It limited cultural knowledge to word meanings, and limited word meanings to tidy models that might not replicate how speakers actually think about meanings or use the words (Quinn, 2011). Contemporary cognitive anthropologists have a variety of approaches to the study of cultural knowledge that will be described in the next section.

Current Knowledge

At present, psychological anthropology includes a rich variety of methods, theories, and topics in the study of subjective experience in cultural contexts. Some psychological anthropologists obtain deep accounts of one person's life story; others observe child rearing; still others measure cortisol levels. Theoretical frameworks come from a variety of sources, including artificial intelligence, narrative psychology, relational psychoanalysis, feminist and critical theories, phenomenology, evolutionary theory, and the neurosciences. The following overview presents some major approaches but cannot describe all.

An important trend in the last 20 years is the emergence of theoretical frameworks that can integrate studies of cognition with studies of emotions, motivations, and personality dynamics. For heuristic purposes, cognitive and psychoanalytic personality studies will be discussed in separate sections, followed by theoretical efforts to bring them together.

Cognitive Anthropology

Cognitive anthropologists study shared and varying beliefs among members of a social group, information processing in particular social contexts, and other aspects of cognition such as memory or interpretive devices such as narrative structures. Some major schools of cognitive anthropology include cultural models, cultural consensus analysis, cognition in practice/distributed cognition, and cultural epidemiology.

Cultural Models

As the limitations of ethnosemantics were becoming more apparent, some anthropologists became interested in new ways of modeling word meanings and other types of cultural knowledge. They turned to the cognitive sciences where, from the mid-1970s on, linguists, psychologists, and others began formulating a way of modeling knowledge now called schemas (or schemata; other names are frames and scripts). The basic insight of schema theory is that explicit beliefs rest on a wealth of sometimes unspoken understandings. These understandings are not of disconnected propositions or features, but are

holistic models that provide context and interrelations. For example, instead of defining grandmother in terms of the features that distinguish this kin term from others (female second-generation ascending consanguineal), a schema analysis of the meaning of grandmother for many contemporary Americans might include a more psychologically realistic description of the kin relation (grandmother is the mother of one's mother or father), as well as expectations about how grandmothers typically behave (spoil their grandchildren), what they are supposed to look like (gray hair and unfashionable clothes), and so on. The idea of spoiling in turn rests on schemas about human nature as well as values about child rearing. All these implicit or explicit understandings are part of or connected to a grandmother schema. Each person has their own schemas; the ones that are learned and widely shared in a social group are cultural models or cultural schemas (Casson, 1981; Holland and Quinn, 1987; Quinn, 2011). Stereotypes are a type of schema because schemas represent simplified, generic knowledge, rather than knowledge of specific cases that may depart from the generic schema. Schemas are shaped not only by recurring patterns of one's first-hand experience but also by the repeated images and ideas propagated through media. Psychologists have found that schemas influenced memory and other aspects of information processing because cuing part of a schema tends to bring the rest of it to mind; thus, people may reconstruct memories to include the elements they expect on the basis of the schemas they hold.

There is no mechanical procedure for uncovering the elements of a cultural schema. Semistructured interviews about the topic in question are generally employed, with interviewees' comments then analyzed for repeated patterns in their explicit statements as well as the unstated assumptions that are revealed in the metaphors they use, their reasoning, and their trains of association (see essays in Holland and Quinn, 1987; Quinn, 2005). Cultural models research has been used to study conflicts between contemporary Chinese parents' explicitly stated values and their more complex implicit cultural models of appropriate behavior (Fong, 2007), Americans' ideas about marriage (Quinn, 1996), and Americans' conflicting schemas about social policy issues such as immigration and social welfare programs (Strauss, 2012).

Some cultural models researchers have proposed that connectionist models of cognition, inspired by the way neurons interact, can explain the ways in which schemas are built up through experience but allow creative responses to new circumstances. In older models of cognition, information is assumed to reside in the form of sentences in the people's minds. Adaptation to novel circumstances can be explained only as new sentences or as highly complex representations (if conditions *p*, *q*, *r*, *s*, and *t* apply, do this) that it is hard to imagine anyone learning. Suppose instead that learning consists of strengthening connections among different networks of neuronlike units that come to be more closely connected when they are activated together. Knowledge on this view is best thought of the weights that make it likely that a certain set of sensory inputs will activate other units and those still others, eventually leading to a particular response. Those weights can be modified by experience, and all the features of a situation will activate a particular set of units specific to that experience, creating the possibility of a new response. Connectionist models are particularly useful for modeling implicit associations and procedural knowledge, i.e., knowledge that is embodied in skills, habits, and associations that may be at odds with explicit beliefs (Strauss and Quinn, 1997).

Cultural Consensus/Cultural Domain Analysis

Consensus analysis was developed by Romney et al. (1986) as a replicable method for studying the extent of agreement in beliefs. The basic assumption is that in many cultural domains there are some agreed-upon propositions among members of a social group, although some people may have greater cultural expertise in that domain (football rules, disease symptoms, or celestial navigation) than others. If the researcher observes a response pattern in which there is convergence among some participants on a set of answers, and no competing agreed-upon answers, the consensual answers are considered cultural knowledge and those who gave the culturally correct responses are considered to have greater competence in that domain (assuming certain conditions hold, such as the respondents are not discussing their answers with each other while taking the test). Consensus analysis is generally conducted with true–false or multiple-choice questions that may be derived from qualitative interviews. This method can also be used to uncover competing understandings of the correct answer, as well as individual differences in knowledge. Like all standardized measures, it limits participants' opportunity to reveal their thinking beyond the questions asked, but the methods usefully reveal cultural and individual differences.

Cultural consensus analysis is one of many standardized approaches (e.g., free listing, pile sorts, and triad tests) used in cultural domain analysis, which is a continuation of earlier ethnosemantic studies of the interrelation of terms in a particular cultural domain (Weller and Romney, 1988). In free listing, participants are asked to simply list a number of terms in a domain (e.g., kinds of illnesses). The next step might be sorting those terms into piles of like items, which indicates taxonomic categories, or judging which out of three terms is the most different, which can reveal the features that are psychologically significant in making judgments of similarity and difference. For example, Moore et al. (1999) found shared bases for differentiating emotion terms among speakers of English, Chinese, and Japanese using these techniques. (See also the much-cited research on color terms of Berlin and Kay, 1991[1969].)

Cognition in Practice/Distributed Cognition

The theories of the Russian developmental psychologist Lev Vygotsky have led other anthropologists to stress the way thinking emerges from activities in particular settings. On this view, cognition is situated in particular social and material settings, with information processing distributed among different objects and social roles in a 'community of practice' (Lave and Wenger, 1991). From this perspective, culture may be defined not as what people know, but what people do. Thus, the primary research method employed is observation of ongoing activities (arithmetic while shopping, Lave, 1988; or navigation on board a ship, Hutchins, 1995), perhaps asking the person being observed to think out loud while they are in the midst of their activity. Nardi (1996) examines human–technology interaction, distinguishing the insights of

activity theory, situated action models, and distributed cognition. While some followers of this approach reject the significance of mental representations such as schemas, others see mental schemas as symbolic creations just like other cultural artifacts that mediate the effects of situational stimuli on human thoughts, feelings, and actions (Hazlehurst, 2011; Holland and Cole, 1995).

Cultural Epidemiology

Cultural epidemiologists are concerned with why some ideas and behaviors are widespread in a population and others are not. Some focus on features that make information easy to remember and in evolved human psychological processing biases, such as attributions of intentionality to others, taxonomic categorization of natural kinds, and the tendency to believe and emulate prestigious others (Boyd and Richerson, 1985; Henrich and Boyd, 1998; Sperber, 1996). Such studies may also take into account environmental factors (e.g., geographical barriers to the spread of knowledge), social ties (social networks, expert networks, and types of intergroup contact), and institutional structures and practices (e.g., authority structures, schooling, and mass media). Cultural epidemiologists have studied why religious beliefs are widespread (Atran, 2002), and the social distribution of ecological beliefs among different Mayan and Ladino groups in Guatemala (Atran et al., 2005), among other topics. The methods of cultural epidemiology draw upon a mix of cultural consensus analysis and distributed cognition approaches. There is overlap between this field and evolutionary anthropology (Barkow et al., 1992), which proposes ways in which minds have been shaped by evolutionary adaptation. These proposals are controversial among psychological anthropologists.

Psychodynamic Approaches and Studies of Childhood

Contemporary psychoanalytic anthropology retains basic Freudian concerns with psychic conflict, tension between conscious and unconscious beliefs and feelings, and the expression of the unconscious in individual fantasies and public culture. Contemporary psychoanalytic anthropologists usually draw upon neo-Freudian theories such as ego psychology, self-psychology, object relations theory, and relational psychoanalysis (Westen, 2001), or poststructuralist psychoanalytic theories such as those of Jacques Lacan. Psychoanalytic anthropologists have also been influenced by ethnographic observations outside of Europe and North America. The result is a greater attention than in classical Freudian theory to the impact of social and cultural contexts, formative psychological development not only in early childhood but later as well, mother–child relationships or interactions with multiple caretakers rather than Oedipal father–son relationships, and creative and adaptive psychological ego defenses more than destructive drives (LeVine, 2010; Paul, 1989). Some psychoanalytic anthropologists reject the assumption of universal libidinal and aggressive drives; others find support for them in newer evolutionary psychological theories of reproductive fitness. Unlike earlier culture and personality studies, the primary goal of contemporary psychoanalytic anthropologists is not to characterize typical personality structures in a society, although researchers may discuss recurrent types of psychic conflicts and ways of dealing with them. At present, psychoanalytic anthropologists typically rely on in-depth research that produces a wealth of interesting data.

Some psychoanalytic anthropologists analyze collective forms of expression, such as myths and rituals, seeing in them socially instituted expressions of and defenses against recurrent psychological concerns, e.g., about gender identity (Herdt, 1994 [1987]). Other psychoanalytic anthropologists are more interested in the personal uses of collective symbols (Spiro, 1987). Such researchers will focus on the lives of particular people to see how they turn collective symbols into personally meaningful ones (Obeyesekere, 1981). Several psychoanalytic anthropologists have studied dreams as revealing a nexus of psychic conflicts and cultural symbolism. For example, Waud Kracke (1981) explores a series of dreams reported by a Kagwahiv Indian man in Brazil that may be disguised reactions to the recent deaths of his two young children, losses that Kagwahiv are supposed to avoid dwelling upon. (See also Hollan, 2003; Mageo, 2011.) Others have suggested that possession trance may be a culturally sanctioned channel for indirect expression and gratification of wishes for those who lack power in other ways, such as women in many societies (Bourguignon, 2004).

Another influence of Freudian theory is continuing interest in child rearing. For example, Jean Briggs's *Inuit Morality Play* (1998) focuses on the social dilemmas that Inuit adults create for young children. Briggs proposes that their teasing questions (e.g., "Why don't you kill your baby brother?" "Your mother's going to die – look, she's cut her finger – do you want to come live with me?") teach children to be highly tuned to hidden social meanings. They also seem to deliberately cultivate ambivalent attachment feelings, which is an interesting contrast with the ideal of secure attachment in Western attachment theory. Studies of child rearing in psychological anthropology do not need to rest on psychodynamic theories, however, to investigate universals and cross-cultural differences in the ways children are raised from infancy onward (LeVine, 2007; *see* Childhood: Anthropological Aspects).

Current and Emerging Directions in Psychological Anthropology

Cognitive and psychoanalytic approaches may appear to be opposing, following the distinction between thought and feeling in Western folk categories, and for a long time they have been treated that way. One of the more interesting developments in recent decades has been efforts toward a more integrated approach to the study of culture and self.

For example, D'Andrade and other cognitive anthropologists have proposed that the cognitive representations of cultural models can be motivating if they represent widely shared goals (D'Andrade, 1992). Other cultural models theorists focus on the way personal experiences may or may not lend emotional and motivational force to cultural schemas for particular persons (Strauss, 1992; Westen, 2001). Connectionist models of schemas can readily incorporate feelings and desires that are associated with features of

objects or events (Strauss and Quinn, 1997). Freud's theory of dream interpretation rested on a similarly associationist model of mind that combined symbols, meanings, and emotions.

While connectionist models are neurally inspired but are models only, other anthropologists have begun to study the interactions of culture and human biology (biocultural studies), including neurobiology (neuroanthropology, Lende and Downey, 2012). For example, Worthman examines the way maternal stress affects in utero environments and their children's neuroendocrine flow, which regulates emotional reactions to traumatic events (Worthman, 2009). Seligman and Kirmayer (2008) discuss the neurobiological and physiological basis of dissociative states, while showing that the way such states are experienced depends on whether they are culturally normative. Quinn draws on neurobiological accounts of fragmentation and integration of self, expanding the notion of self beyond conscious self-representations (2006). Much of this research moves away from explicit beliefs to stress the way bodily habits, implicit mental associations, and emotions are developed through people's experiences in specific sociocultural settings. The emerging work in this area is not neurally reductive; instead, the goal is to think about the interrelationships of body, mind, and context.

From the other side, anthropologists whose primary interest is in emotions, mental illness, or child rearing have become interested in the shared schemas that shape the way emotions and mental illnesses are conceptualized or the folk theories of human nature or child development that affect practices of child rearing. Psychiatric anthropology is an interesting example of convergence among different theoretical approaches. Both mainstream Western psychiatry and psychiatric anthropology have moved away from Freudian approaches to mental illness, but they have gone in different directions. Contemporary psychiatrists usually stress biomedical definitions of mental illness, while contemporary psychiatric anthropologists try to broaden discussion of mental illness to encompass subjective personal experience and larger social and cultural contexts, including folk theories of psychology (ethnopsychology).

Interest in narrative is another area of convergence between psychoanalytic and cognitive anthropologists (Garro, 2001). Personal narratives rely upon shared cognitive schemas of typical story structures and life course sequences. Telling a story rehearses and fixes some memories; not telling elides other memories. At the same time, clinical practice is increasingly focused not so much on revealing true memories but on helping patients to construct more adaptive narratives relating themselves to others (Paul, 1989). Whether starting with more cognitive or more psychoanalytic concerns, anthropologists are often as interested in how people tell their life story as in the historical record of the facts relayed, unlike life story research in sociology or history. Ordering experience in emotion-laden narratives and other cultural schemas is part of a larger 'effort after meaning' that the mid-twentieth-century psychologist Frederick Bartlett said was part of all human cognition (Garro, 2001: p. 110).

Another important development in psychological anthropology is to place subjective experience in a larger social and political context. Psychological anthropologists are concerned with the subjective experience of unequal power relations, violence, stigma, suffering, and with the development of political consciousness and various kinds of group identities (see the essays in Casey and Edgerton, 2005; Mageo, 2002; Quinn and Strauss, 2006).

Methodological and Theoretical Issues

Tribal differences among psychological anthropologists are often based on preferred methods. For example, even though cultural models and cultural consensus researchers are both concerned with the content of cultural beliefs, their methods differ. Cultural models research relies on qualitative analysis of lengthy semistructured interviews; cultural consensus analysis draws upon quantitative analysis of responses to standardized questions. Cultural models researchers believe their approach to be more revelatory of implicit beliefs; cultural consensus researchers stress the replicability of their methods. In practice, however, cultural consensus analyses usually begin with the more open-ended approaches that are typical of cultural models research, and members of both camps would agree on the importance of person-centered empirical research as opposed to, say, methods that draw inferences about people's beliefs from collective expressions such as rituals or movies.

Psychological anthropologists have differed in the past over the extent to which there are universals of human psychology. Some declare that mainstream academic psychology is only a Western folk theory. While most would not endorse such a sweeping dismissal, psychological anthropologists over the years have questioned the cross-cultural applicability of particular psychological theories, from Freud's Oedipus complex and Piaget's presumed universals of cognitive development to Bowlby's theories of attachment (see LeVine and Norman, 2001; Quinn and Mageo, 2013) at present. Criticism of particular theories does not imply rejection of all psychological theories. If people are acquiring different folk theories of psychology, then culture learning is occurring, which can only be explained by reference to general psychological theories. Cross-cultural comparative research has produced important findings about the interacting effects of universal tendencies and variable experiences in realms ranging from the effects of father's absence on boys' sex-typed behavior to emotion concepts (Munroe and Munroe, 2001).

Although there is no unanimity about what psychological universals there may be, universalism versus particularism is not a central debate at present. Instead of either–or debates, current research draws eclectically on a variety of approaches that reveal the complexity of the ways brains and bodies are shaped in particular settings to create people's interpretations, experiences, and practices.

Electronic Resources

The Society for Psychological Anthropology (SPA), a section of the American Anthropological Association, maintains a Web site with links to syllabi, graduate programs, prizes, funding, and conferences sponsored by the society. The SPA listserv creates opportunities for distant researchers to connect (http://www.aaanet.org/sections/SPA/).

The Neuroanthropology blog is frequently updated with articles and links of broad interest to anthropologists interested in the mind (http://blogs.plos.org/neuroanthropology/).

The Foundation for Applied Psychiatric Anthropology provides links to information about films, books, articles, conferences, organizations, and other resources (http://www.psychanthro.org/FAPA_Home.html).

Abstract

Research in psychological contracts at work continues to expand and advance. In this article, we summarize and integrate this scholarship, addressing definitional issues, theoretical perspectives, plus antecedents and consequences of psychological contract breach (PCB). We identify future research opportunities that can enrich our understanding of PCB and its consequences for employees' work attitudes and behaviors.

Over the last two decades, the concept of psychological contract (Rousseau, 1990) has received much theoretical and empirical attention in organizational behavior and industrial/organizational psychology (e.g., Zhao et al., 2007). Spawning much of this interest has been the changing nature of the employee–organization relationship (Rousseau, 1995). Early writings on the psychological contract trace back to Argyris (1960) and Levinson et al. (1962) who loosely referred to psychological contract to describe the subjective aspects of employment relationships, referring to the unspoken agreement between supervisors and employees or the unconscious psychological needs (i.e., affection, dependence, aggression, growth, and development) that affect and define expectations forming within the employee–organization exchange relationship. Although the majority of scholarship emphasized needs and expectations as the primary concepts characterizing psychological contracts, Rousseau (1989) challenged these long-standing assumptions by redefining the psychological contract, thus reinvigorating scholarly interest in the construct.

Accordingly, psychological contracts capture "individual beliefs, shaped by the organization, regarding terms of an exchange agreement between individuals and their organization" (Rousseau, 1990: p. 9). Departing from conventional wisdom emphasizing the role of psychological needs, Rousseau (1990) argued that beliefs regarding the terms of the psychological contract are grounded in the explicit (e.g., verbal and written agreements) or implicit (e.g., repeated patterns of exchange) promises employees perceive their organization to have made (e.g., job security, bonuses) in exchange for their contributions (e.g., commitment and performance). Hence and importantly, employees' psychological contracts consist only of those obligations that are grounded in perceived promises. Besides its promissory nature – which distinguishes the psychological contract from more generic employment expectations (e.g., Robinson, 1996) – Rousseau (1989, 1990) described three additional characteristics of psychological contracts. First, they are perceptual and idiosyncratic, and hence held and understood by the employee alone: that is, mutual understanding of or agreement between employee and employer regarding the contract's content is not a necessary condition (Rousseau, 1995). In this way, psychological contracts differ from formal or implied contracts, which consist of commonly understood or shared beliefs (Morrison and Robinson, 1997).

Second, Rousseau (1990, 2000) identified a typology (transactional, relational, and balanced) of psychological contracts along dimensions of time frame (short-term versus open-ended), degree of specificity (highly versus loosely specified), resources exchanged (tangible versus intangible), and performance–reward contingency (highly contingent versus low or noncontingent). Accordingly, transactional contracts have a short-term and narrow focus, where tangible resources are exchanged for specific times and tasks (e.g., an employee is promised commission-based pay contingent upon meeting performance objectives); relational contracts involve highly subjective, open-ended exchanges that are based on trust between employee and organization (e.g., employee is promised developmental opportunities in exchange for extrarole services); while balanced contracts blend features of transactional and relational arrangements and allow for greater flexibility and changing contract requirements (e.g., employee is promised advancement opportunities in exchange for escalating performance requirements). Psychological contract scholarship has largely emphasized the transactional-relational distinction (Zhao et al., 2007).

Third, Rousseau (1989) speculated that psychological contract violation – or the "failure of organizations or other parties to respond to an employee's contribution in ways the individual believes they are obligated to do so" (p. 128) – constitutes the main process through which psychological contracts impact employees' attitudes and behaviors. This perspective differed from earlier views, which tended to focus on the discrepancy between employee and employer expectations (e.g., Schein, 1980), or thwarted needs (Levinson et al., 1962), regardless of what was promised. Rousseau's (1990) reformulation, has dominated much of the scholarly writing on the effects of psychological contracts on employees' work-related attitudes and behaviors (Zhao et al., 2007). Indeed, there is a wealth of empirical evidence to confirm that psychological contracts matter because failing its (even implicit!) terms (now commonly referred to as psychological contract breach (PCB); Morrison and Robinson, 1997) can result in significant negative consequences for employees and organizations (Zhao et al., 2007).

Overall, Rousseau's (1989, 1990) reformulation advanced greater precision for understanding conceptual and theoretical underpinnings of the psychological contract. More importantly, by introducing and highlighting process mechanisms such as violation (or PCB), her work triggered an explosion of empirical studies focused on the antecedents and consequences of PCB. Building on these insights, scholars have also explored consequences of psychological contract fulfillment (Turnley et al., 2003), including overfulfillment (i.e., delivering more than what was promised; Lambert et al., 2003). Generally speaking, fulfillment of psychological contract obligations elicits positive employee responses, which, however, begin to diminish as delivered inducements exceed promised inducements (overfulfillment). While contract fulfillment is an interesting area and our literature review aims to be broad, we pay particular attention to the state of literature addressing PCB because this is and has been the focus of the theoretical and empirical scholarship (e.g., Zhao et al., 2007).

Theoretical Perspectives

Several theoretical perspectives have been used to explain why PCB results in negative consequences. The underlying theoretical frameworks in psychological contract research include equity theory, social exchange theory, and the group value model.

Equity Theory

Equity theory proposes that individuals estimate the ratio of what has been contributed (i.e., inputs) to what has been received (i.e., outcomes) for both themselves and a chosen referent other (Adams, 1965). Inputs are the employee's contributions (e.g., education, performance, work experience), while outcomes constitute rewards that employees receive in exchange for their contributions (e.g., compensation, promotions, career development opportunities). If an imbalance between inputs and outcomes occurs, individuals are likely to reduce the discrepancy by adjusting their attitudes, contributions, or outcomes to restore the balance between the two ratios.

Social Exchange Theory

Scholars have utilized this theory to conceptualize social exchange in the workplace as a series of mutual, obligation-based exchanges between interdependent parties (Blau, 1964). Exchanges at work are often governed by reciprocity norms (Gouldner, 1960) such that when individuals receive something from another individual, group, or organization, they feel compelled to reciprocate, typically in kind (i.e., positively or negatively). Moreover, the theory differentiates between two types of exchanges (Blau, 1964), with social exchanges involving unspecified obligations and economic exchanges encompassing specified obligations. Notably, social exchanges require trust between parties whereas economic exchanges do not. In the context of psychological contracts, when employees believe that the organization has not adequately fulfilled its obligations as promised, they may become motivated to reciprocate this unfavorable treatment. Such negative reciprocity, may take the form of reduced loyalty or withdrawal of extrarole services, or in some cases, intentional efforts to harm the organization and its members (e.g., Restubog et al., in press; Zhao et al., 2007).

Group Value Model

Inspired by social identity theory (Tajfel and Turner, 1979), the group value model posits that the manner in which employees are treated by organizational authorities communicates consequential identity-relevant information. Because authorities act as prototypical representatives of groups, employees perceive them to express group norms and being salient indicators of what the broad group membership thinks. Fair and respectful treatment by authorities suggests that the employee is a valued group member, whereas unfair treatment signals occupying a marginal position within the group/organization. Importantly, the fairness of decision-making procedures also sends symbolic messages about whether members can take pride in their group or organizational membership(s). If authorities publicly display fair procedures, it hence helps foster pride and identification among members within that group. These processes are significant because individuals become attached to their organizations by integrating perceived attributes of the organization into their own self-concept (Ashforth and Mael, 1989). In contrast, authorities behaving unfairly signals that group members are unworthy of respect or pride. The group value model is particularly useful in explaining responses to PCB when symbolic issues are involved. Responses to PCB are likely to be more pronounced when the nature of the PCB is relational rather than transactional, as the former emphasizes long-term commitment and socioemotional elements in the employment relationship.

Theoretical Distinctions between PCB and Related Constructs

PCB captures "the employee's perception regarding the extent to which the organization has failed to fulfill its promises or obligations" (Zhao et al., 2007: p. 649). Paralleling the idiosyncratic nature of psychological contracts, employees might perceive PCB, regardless of "whether a promise was actually broken, or even whether an obligation was ever established" (Robinson and Morrison, 2000: p. 526). In other words, PCB need not be real to be perceived, such as when employees misinterpret information received during on-the-job socialization (e.g., "people tend to get promoted rapidly here"; Robinson and Morrison, 2000: p. 526). Earlier, confusion existed regarding the distinction between PCB and unmet job expectations, with the latter referring to employees' job experiences in comparison to their prehire expectations (Wanous et al., 1992). Indeed, some scholars even speculated that PCB would not contribute anything beyond the effects of unmet expectations (Guest, 1998). However, the experience of PCB has been shown to go beyond unmet expectations, because PCB denotes that promises have been broken, and thus norms governing reciprocal exchange (i.e., good faith, fair dealing, and trust) have been dishonored (Morrison and Robinson, 1997; Robinson, 1996). In a longitudinal study of MBA graduates, for example, Robinson (1996) found that PCB explained variance

beyond that accounted for by unmet expectations in predicting organizational citizenship behavior (i.e., employee behaviors that are not formally sanctioned but greatly contribute to organizational functioning; Organ, 1988). Similarly, Zhao et al. (2007) concluded that, relative to unmet expectations, PCB elicits stronger effects on a range of outcomes, including job satisfaction, turnover intentions, and job performance.

PCB also differs conceptually and empirically from the experience of psychological contract violation. In the past, researchers used the terms breach and violation interchangeably until Morrison and Robinson (1997) introduced the now commonly accepted distinction. Accordingly, PCB represents the cognitive awareness that the organization has broken promises, whereas violation represents the affective state (e.g., anger, frustration, bitterness) that may or may not accompany this awareness.

Antecedents and Consequences of PCB

To date, psychological contract scholars have overwhelmingly studied the consequences of PCB relative to its antecedents. Yet the few existent exceptions have identified a range of antecedents (mostly exchange-based), including supervisors' experience of PCB (Bordia et al., 2008), leader–member exchange (LMX; Henderson et al., 2008), supervisor–subordinates (dis) similarity (Suazo et al., 2005), lack of trust (Robinson, 1996), informal socialization (Robinson and Morrison, 2000), history of PCB (Lo and Aryee, 2003), organizational and employee performance (Robinson and Morrison, 2000), and personality (Raja et al., 2004). In contrast, there is a solid body of work examining employees' responses to PCB. This is particularly relevant as it illustrates how social exchange theory, equity theory, and the group value model can be used to explain employee outcomes. To integrate and succinctly present the large volume of literature on the consequences of PCB, we organize our review around the following outcome categories: attitudes, affective reactions, and work behaviors.

In terms of employee attitudes, PCB is negatively related to job satisfaction (Bal et al., 2013), trust (Restubog et al., 2008; Robinson, 1996), commitment (Restubog et al., 2006), and identification, while being positively associated with turnover intentions (Dulac et al., 2008), revenge cognitions (Restubog et al., in press), and cynicism (Johnson and O'Leary-Kelly, 2003). With respect to affective reactions, PCB is positively related to feelings of violation (Restubog et al., in press), negative affect (Lo and Aryee, 2003), and emotional exhaustion (Johnson and O'Leary-Kelly, 2003) but negatively to enthusiasm (Conway and Briner, 2002). Finally, in terms of behavioral reactions, PCB generally leads to more workplace deviance (Restubog et al., in press), reduced in-role (Zhao et al., 2007) and extrarole performance, including citizenship behavior (Zhao et al., 2007), proactive behavior (Bal et al., 2011), and innovation (Ng et al., 2010).

Moderators of PCB–Outcomes Relationships

Researchers have also made considerable advances identifying boundary conditions that impact employees' perceptions of and reactions to psychological contract-related issues, with the majority of studies having investigated moderators that either amplify or ameliorate the effects of PCB and that fall into one of two categories: individual differences or situational influences.

Person Factors as Moderators

Early psychological contract research investigated the potential of attitudes – such as trust – and personality characteristics – such as equity sensitivity, attribution style, and agreeableness – to moderate relationships between PCB and work-related outcomes. For instance, a longitudinal study by Robinson (1996) found that initial trust in one's employer at the time of hiring moderated the PCB-subsequent trust relationship such that low initial trust led to a stronger decline in subsequent trust after perceived PCB compared to high initial trust. Another moderator is equity sensitivity that captures individuals' levels of sensitivity toward unfair situations, with entitled individuals emphasizing personal outcomes and exhibiting a low tolerance for being underrewarded in contrast to benevolents' higher tolerance, which stems from their concern for the employer–employee relationship. Unsurprisingly, research has found entitled individuals to generally respond more negatively to PCB than their benevolent counterparts. In the context of specific PCB facets, for example, those with a more entitled orientation reacted more adversely to breaches impacting tangible extrinsic outcomes such as pay or benefits and to breaches impacting growth and development opportunities; yet benevolent employees exhibited more negative responses when the employer broke promises about autonomy and control (Kickul and Lester, 2001). Concerning global effects of PCB, entitled as opposed to benevolent individuals engaged in less organizational citizenship behaviors and in more interpersonal workplace deviance following PCB (Restubog et al., 2007). Notably, Coyle-Shapiro and Neuman (2004) have attributed null findings involving equity sensitivity to the construct being overly broad, instead advocating the usage of exchange and creditor ideologies because they capture responses to social exchange issues more proximally. Accordingly, these ideologies not only impact individuals' orientation toward exchange relationships with employers in general but also perceived employer obligations and the fulfillment of those obligations in particular. In support, their study showed that individuals subscribing to an exchange ideology closely monitor what their employer is obligated to provide and make their contributions contingent upon the employer's potential inducements, whereas individuals endorsing a creditor ideology over match employer-provided inducements because they believe in repaying more than they receive.

More recent psychological contract research has extended the above list of variables by examining the moderating role of individuals' age and future time perspective (FTP). In a longitudinal study, Bal et al. (2013) reported weaker associations of PCB with job performance – partially mediated by job satisfaction – for older workers, irrespective of PCB type (i.e., economic, socioemotional, or developmental). A related, interesting moderator is FTP, which reflects individuals' belief about how much time they have left in the future (Bal et al., 2010). Accordingly, high FTP individuals have more

active coping styles and focus on the future, including future rewards, learning, and long-term exchanges, while low FTPers exhibit more passive coping styles and focus more on personal than organizational relationships. It follows that organizational inducements in the form of economic and social emotional fulfillment should have a stronger potential for high FTP employees to increase motivation and induce stronger felt obligations. In support, a study by Bal et al. (2010) showed that high FTP moderated positively the relationships between economic and socioemotional psychological contract fulfillment and employee obligations, whereas low FTP yielded nonsignificant or even negative effects in a sample of postretirement employees (i.e., those who continue working past retirement age).

In deliberating the wider implications of the above study results, it is instructive to consider works that have employed emotion regulation as well as the Big Five personality dimensions, as moderators of PCB. Framing PCB as an affective event, Bal et al. (2011) found emotion regulatory strategies to moderate the negative impact of PCB, with cognitive change buffering detrimental PCB effects on feelings of psychological contract violation and on the proactive employee behaviors of sharing knowledge and taking charge at work; yet attentional deployment forms of emotion regulation accentuated the negative effects of both social and generative forms of PCB on those proactive behaviors. Regarding conscientiousness, Orvis et al.'s (2008) longitudinal study showed, as expected, that low-conscientious employees answer to PCB with decreased organizational loyalty and job satisfaction plus with increased turnover intentions; yet unexpectedly, they also found that it is those high in conscientiousness who subsequently reduce their levels of task performance. Finally, Ho et al. (2004) found that agreeableness interacted with PCB severity and type such that its association with trust in the other party weakened only for severe cases of social breach, but not for economic ones.

Situational Factors as Moderators

Psychological contract scholars acknowledge employees' interpretations of the situational context in their studies (e.g., Morrison and Robinson, 1997). Examining the role of organizational justice, for example, Kickul (2001) found a three-way interaction in predicting workplace deviance such that PCB resulted in more deviant behavior when both interactional and procedural justice surrounding the PCB were low. Similarly, Turnley and Feldman (1999) found that PCB was more likely to trigger job search behaviors when employees perceived low procedural justice, external job opportunities, and the PCB as not sufficiently justified. These proximal factors are augmented by research that has investigated more distal contextual/cultural influences. For example, a study with Filipino nationals demonstrated that PCB elicits more negative reactions among those high in workplace familism (i.e., those who hold strong expectations of being cared for and nurtured by organizational agents, especially their supervisors; Restubog and Bordia, 2006). In a similar vein, the notion developed above – that variables cannot be assumed to function with PCB in a uniform fashion simply based on their inherent qualities – also applies to leader–member relationships. For instance, Restubog et al. (2010) contrasted the traditional social support perspective of LMX, which suggests that LMX minimizes PCB's adverse impact on work performance, with a betrayal perspective positing high LMX to aggravate negative effects, and found support for the latter.

Future Research Opportunities

We propose two research directions to broaden and enrich psychological contract scholarship. The first opportunity relates to theoretical framing of psychological contract development and the effects of PCB by integrating Conservation of Resources (COR) theory (Hobfoll, 2001). COR theory submits that individuals (1) are motivated to create, maintain, and increase their stock of valued resources and (2) experience stress when resources are lost or threatened. Given that psychological contracts are fundamentally based on exchange of valued resources (Bal et al., 2010), subsequent inquiries might adopt a resource-based perspective on psychological contracts to identify a broader range of resources exchanged beyond those captured by transactional and relational dimensions. Regarding theoretical framing of the effects of PCB, most previous inquiries have invoked the negative reciprocity principle (Gouldner, 1960) of social exchange theory, which implies that the only possible employee reaction to PCB is a withdrawal of effort or contribution. Yet employees can sometimes react proactively and constructively to negative states within the workplace (Zhou and George, 2001), which is not easily explained by the reciprocity principle. However, COR theory – with its focus on motivation to obtain, retain, foster, and protect valued resources – can explain proactive employee efforts to recover from PCB. Specifically, Hobfoll (2001) delineated several propositions related to resource loss, plus the conditions under which individuals are likely to pursue proactive coping in response to resource loss. In general, the theory posits that individuals well-endowed with resources (e.g., social support, self-efficacy, time) are more likely to respond to resource loss with proactive efforts to acquire additional resources to offset or compensate the loss. In the context of psychological contracts, it is possible to conceptualize PCB as an experience of resource loss (e.g., Restubog et al., 2013), as the core definition of PCB implies that valued resources (e.g., training, development, pay) were not provided. By offering a theory-based explanation for why and under what circumstances employees might respond to PCB in a proactive and constructive way, COR theory can hence broaden our understanding of PCB effects, along with potential moderators that condition PCB effects.

A second future research opportunity relates to advancing normative psychological contracts. Most research in this area has treated psychological contracts as individually held beliefs, even though there are theoretical and empirical grounds to suggest that individuals working in teams develop shared beliefs toward their job and working environment (Rousseau, 1978). Employment experiences such as poor management and unsatisfactory working conditions are likely to be shared by team members, and these experiences have been documented to impact work attitudes (Rousseau, 1978). Indeed, the psychological contract literature suggests that individuals belonging to the same team tend to exhibit normative behavior (Coach and

French, 1948), affect (George, 1990), and job attitudes (Pfeffer, 1980). Following this line of reasoning, it can be argued that the commonality of the work environment experienced by team members should contribute to the formation of shared psychological contracts. Social information processing theory (Salancik and Pfeffer, 1978) suggests that social information cues facilitate shaping interpretations about job and work environments, including the employing organization. For example, Rousseau and Greller (1994) noted that employees develop an understanding of their psychological contract from a wide variety of sources, which may include organizational agents (e.g., senior managers), or organizational structures and systems (e.g., company policies) that create obligations on behalf of the employer. Along similar lines, team members are potent sources of information because they typically provide their own subjective evaluation of the organization, which they likely discuss with coworkers. In support, Dabos and Rousseau (2004) found that network interaction among employees contribute to the formation of psychological contract beliefs. Hence, exposure to similar communication networks increases the propensity for team members to develop similar beliefs and assumptions about their job and organization. We can refer to this group level construct as 'normative psychological contracts,' defined as *employees' shared mental models concerning what the organization is obligated to provide to the work team*. Future inquiries might validate this proposed construct and explicate its antecedents, processes, and outcomes.

Abstract

Empirical evidence supports the efficacy and effectiveness of psychological treatments for a wide variety of psychological disorders. It appears that about two-thirds of patients secure positive outcome even though the problems they are struggling with have been long-standing. The gains that are made can be achieved very rapidly in many cases (first five sessions) with more disturbed patients taking longer to return to a state of normal functioning. Positive outcomes are maintained over follow-up periods of 2–5 years. Changes appear to be due to factors common across theory-based treatments.

Introduction

Empirical evidence supports the effectiveness of psychotherapy. Researchers in the field have confirmed empirically that psychotherapy produces beneficial and relatively lasting effects. Contributions from the dose-effect literature suggest that patients improve as the number of sessions increases with diminishing returns at higher dosage levels. Factors important for patient improvement are generally considered features common across rather than unique to particular theories of psychotherapy. Despite intentions to facilitate improvement, a small percentage of patients seem to deteriorate while participating in psychotherapy treatment.

The Definition of Psychotherapy

In general, psychotherapy is a collaborative enterprise (between a trained professional clinician and patient) developed to provide relief from problematic symptoms and help prevent future relapses, support desired personality change, enhance adaptive role functioning in relationships and at work/school, increase the ability to make healthy life choices, and promote overall quality of life through helping patients to negotiate challenges and make changes in their behaviors, emotions, cognitions, and/or other characteristics. Approaches to psychotherapy are numerous and diverse including orientations such as cognitive, behavioral, psychodynamic, humanistic, and eclectic combinations of these theory-based orientations.

The Effectiveness of Psychotherapy

Over the past 40 years, a myriad of research designs, methodologies, and meta-analytic investigations have combined to create a sizable body of scientific evidence that attests to the effectiveness of psychotherapy across diverse settings (hospitals, counseling centers, clinics, military, public health, primary care, etc.), conditions (diagnoses, addictive, health, psychological, and relational problems), and populations (adults, children, adolescents, and older adults; Burlingame et al., 2013; Hofmann and Smits, 2008; Lambert, 2013; Sexton et al., 2013; Weisz et al., 2013). Overall, research has demonstrated that psychotherapy interventions are efficient, safe, demonstrate efficacy across most diagnostic conditions, and have far-reaching effects. Assessments (via self-report, therapist/expert evaluations, evaluations of significant others, and/or societal records) of the benefits of psychotherapy have focused on such domains as reduction in symptoms, increase in problem-solving skills, enhanced health, and improvements in interpersonal/social functioning. Reviews of this literature have confirmed the beneficial effects of therapy concluding that treated patients consistently fare better than untreated patients; in fact, research reveals that 65% of treated patients can expect to have a positive outcome as compared to only 35% of patients who receive no treatment during the same period of time (Lambert, 2013).

Furthermore, when compared with interventions like psychopharmacology, the results of psychotherapy tend to last for longer periods of time with lower relapse rates in many cases. Moreover, given that patients often acquire new knowledge and a variety of useful skills during the course of treatment that they continue to utilize after the treatment has ended, it is common for patients to experience further improvement following treatment termination. Moreover, psychotherapy has proved to be very cost-effective as it often pays for itself in terms of medical cost offset (as patients engaged in psychotherapy are less likely to use inpatient medical services, tend to have significantly shorter hospital stays, etc.), life satisfaction, and increased productivity in work and home roles (e.g., Chiles et al., 1999; Crane, 2008).

Treatment Duration and Lasting Effects

In contrast to the length of treatment associated with psychoanalytic psychotherapy (which often lasted years with multiple visits per week), the extant literature suggests that substantial benefits from treatment occur in relatively short durations (e.g., 14 weekly sessions), and equally important, these gains are maintained over substantial periods of time. Examinations of changes over weeks of treatment have confirmed a positive response to treatment as the dose (i.e., number of sessions) increases, with diminishing returns at higher dosage levels. Studies from the dose-effect literature suggest that, for many

clinical disorders, a range of 10–20 sessions is sufficient for 50% of patients to return to normal functioning (Harnett et al., 2010). Moreover, promising results occur as the dosage level is increased to the extent that 75% of patients can be expected to recover substantially after 26–50 sessions (Hansen et al., 2002).

Although a majority of patients experience significant benefits from psychotherapy, there is also evidence that the more disturbed a person is at the outset of therapy, the longer (more sessions) it will take for them to return to a normal state (Lambert et al., 2001). Observed trends in patient improvement have led some researchers to propose a phase model of recovery in which personal welfare, symptom reduction, and interpersonal/social functioning improve in sequence (Kopta et al., 1994).

In addition to results supporting relatively short recovery periods for a majority of patients, there is evidence that beneficial gains from psychotherapy are enduring. Although adjustment from psychotherapy treatment does not prevent recurrences of psychological disturbance, it appears that many patients maintain healthy functioning for prolonged periods of time subsequent to treatment (Dugas et al., 2010). However, exceptions to the notion of lasting treatment gains are noted in work with patients who are obese, have substance abuse, eating disorders, or who are suffering from symptoms of recurrent depression or personality disorders. Conversely, research has also detected a large minority of patients, perhaps 30%, who are able to attain benefit from therapy after a surprisingly small number of sessions (three to five); these clients are said to have 'sudden gains' or 'early dramatic treatment response' and approximately 80% have been found to maintain gains and remain improved 1 year later (Haas et al., 2002).

Factors Important to Psychotherapy Outcome

In addition to the research focused on examining the effectiveness of psychotherapy, considerable emphasis has been placed on the factors that contribute to positive patient outcome. Findings from this research fall into three general categories: patient variables, common variables, and specific intervention variables.

Patient Variables

The patient is most likely to determine successful outcome. The literature focusing on the study of patient variables is too voluminous to repeat, and thus only the most important findings are reported here. Each patient entering treatment brings a diverse array of factors when presenting to the clinician. These include different psychological disorders, historical backgrounds, stresses, personality structures, and the quality of their social support networks, to name just a few. Patient variables found to have relationships with outcome are severity of disturbance, motivation and expectancy for treatment, capacity to relate, integration, psychological mindedness, and ability to recognize relevant problems (Bohart and Wade, 2013). Therefore, patients suffering from challenging symptoms as well as relative deficits in numerous patient variable categories are likely to experience negligible improvement during treatment. For example, the borderline, alcoholic patient with suicidal tendencies who is forced into treatment, believing that most marital problems are a result of an insensitive spouse, is likely to benefit less from treatment than the depressed patient who voluntarily begins treatment and is determined to make personal changes that will lead to marital harmony (Sexton et al., 2013).

Although patient variables have been conveniently categorized, the impact each has on the outcome of therapy is not equal. In general, the severity of disturbance is the patient variable that is most related to the outcome of the treatment (Garfield, 1994). Patients with serious mental disorders, such as the schizophrenic, schizoaffective, and bipolar disorders are typically treated primarily with psychopharmacological management, suggesting the challenge these disturbances provide for psychotherapy alone (Forand et al., 2013). Personality disturbances also appear resistant to change in the short-term use of psychotherapy (i.e., 12 sessions).

Common Factors

Because outcome researchers have consistently failed to find sufficient evidence indicating superior improvement of patients as a consequence of receiving a particular kind of psychotherapy, some have concluded that psychotherapy equivalence is a result of factors common to all psychotherapy (Cuijpers et al., 2012; Grawe, 2002). Common factors propose the possibility that there are components utilized in therapy that are curative and universal – regardless of specific school or theory of change – which include support, learning, and action elements (Lambert, 2013). The developmental nature of the support–learning–action sequence presumes that the supportive elements precede modifications in attitudes and beliefs which, consequently, precede the clinician's attempts to encourage client action. It is presupposed that all therapies provide for a collaborative working enterprise wherein the client's sense of safety, trust, and security (along with resultant decreases in anxiety, threat, and tension) lead to changes in conceptualizing problems and, ultimately, in behaving differently by taking informed risks to talk about a sensitive concern, experiment with new coping skills, problem-solve through purposely exposing oneself to anxiety-producing situations, and/or engage in other growth-promoting behaviors that are commonly challenging and distressing.

More specifically, it has been proposed that the therapist–client relationship is a common factor crucial to positive treatment outcomes that has multidimensional and substantial research base (Wampold, 2001). While techniques are influential, the extent to which unique methods can be used to effect change is largely determined by the nature of the relational context in which they are employed. In clinical trial studies comparing multiple treatments for particular psychological disorders, patients' positive assessment of the therapeutic alliance is one of the best predictors of psychotherapy outcome (e.g., Krupnick et al., 1996). If factors like acceptance, trust, kindness, understanding, warmth, and human consideration are not present, it is unlikely that the interventions utilized will result in desired transformation. Furthermore, a systematic review of psychotherapy research by Norcross and Lambert (2011) on the role of relationship factors in therapy revealed that empathy, alliance, and collecting client feedback were all 'demonstrably effective' in

facilitating positive therapy outcomes while positive regard, goal consensus, and collaboration were found to be 'probably effective' components of therapy (*see* Therapist–Patient Relationship).

However, although a significant amount of evidence points to common factors as mediators of patient change, the notion of beneficial techniques unique to specific therapies cannot be ruled out, as occasionally such interventions can be shown to contribute to successful outcomes in patients independent of common factors (*see* Psychological Treatments: Randomized Controlled Trials).

Specific Interventions

The American Psychological Association and other professional associations in other countries (e.g., Germany and England) are constantly in the process of developing clinical treatment guidelines (e.g., National Institute of Health and Care Excellence (NICE) guidelines in the United Kingdom) that can help identify particular treatments and procedures that research has demonstrated to be most effective with specific problems and/or patients. The evidence for treatments is usually judged to be strongly supported (SS) or moderately supported (MS) based on the kind and amount of evidence that has accumulated (see Chambless and Hollon, 1998; for an example of one rating system). One should keep in mind, however, when reviewing the following sections that denote specific therapeutic approaches that the empirically supported treatments that are summarized are not necessarily uniquely effective nor are the outcomes in most cases so superior to other forms of therapy to justify their sole promotion or use. In fact, as stated prior, differences in outcome when comparing various forms of therapy are most often not as distinct as expected, hoped for, or insinuated.

Moreover, other significant obstacles to this type of specificity and approach arise including the sheer number of therapeutic approaches/theories that exist (which is in the hundreds if not the thousands), the constant evolution of therapies subsequent to research and in its absence, and the emergence of new methodologies that appear promising. Some would argue that it is not reasonable to expect a single therapist to sufficiently master the number of therapies it would require to serve a general clientele given that the number of discrete disorders surpasses 300. The expense, impracticality, and lack of research evidence on so many therapies with so many disorders may prove insurmountable. Furthermore, most often clients present with a myriad of complex symptoms and circumstances of life that do not easily fall into definite categories to be matched up with a single clear-cut treatment.

Lastly, as mentioned before, while technical proficiency undoubtedly makes a unique contribution to therapy, any efforts to propagate a best practice or an empirically supported psychotherapy while dismissing the impact and importance of the therapeutic relationship is potentially misleading and incomplete (Norcross and Wampold, 2011) as it is this positive interpersonal affective environment that often stimulates patient improvement in the therapeutic encounter. Nevertheless, at least empirically supported treatments have been rigorously tested and undergone the peer review necessary for publication and there is some information about their comparative effects. We support the clinical use of empirically supported treatments over treatments with no empirical evidence.

Anxiety

Specific disorders within the anxiety spectrum for which particular techniques have been researched include generalized anxiety disorder (GAD), panic disorder, and posttraumatic stress disorder (PTSD).

Generalized Anxiety Disorder

The basic premise of cognitive behavioral therapy (CBT) for GAD (SS) is that thoughts, behaviors, and feelings are interconnected and so using an intervention to change one aspect (e.g., behavior) can lessen difficulties in the others (e.g., thoughts and feelings). CBT typically refers to a treatment wherein combinations of cognitive and behavioral techniques are utilized in the same course of treatment. In CBT for GAD, these interventions might include modifying negative thinking (e.g., that worrying is beneficial in some way), taking part in relaxation training, planning pleasurable activities, and/or intentional exposure to avoided situations that are objectively safe to learn that anticipated, feared outcomes do not occur. CBT for GAD typically encompasses 16–20 sessions over a 4-month period. Acceptance and commitment therapy (ACT) for GAD (MS) is a behaviorally based intervention that focuses on acceptance, rather than avoidance, of internal experience (which in GAD typically includes the unwanted emotion of anxiety, anxiety-inducing thoughts, and/or bodily sensations like racing heart, sweating, rapid breathing, etc.). Through using defusion and mindfulness techniques, patients are able to reduce avoidance and commit to behaving in ways that are consistent with chosen values (listed with support for chronic pain, depression, anxiety, obsessive–compulsive disorder (OCD), and psychosis).

Panic Disorder

CBT (SS) has strong research support for treating panic disorder. Most frequently, the therapist utilizes a combination of psychoeducation (about panic/fear and the body's physiological response), cognitive techniques (helping the patient identify, evaluate, and modify problematic thoughts related to panic such as perceived catastrophic consequences of specific places, people, bodily sensations, feelings, etc.), and exposures that incorporate *in vivo* (e.g., intentional approach of real-world, trauma-related situations that are objectively safe yet have been avoided previously due to trauma-related fear) and/or interoceptive (e.g., inducing bodily sensations like a racing heart, trouble breathing, dizziness, and sweating) aspects. CBT for panic is typically 12–16 sessions and can be delivered in either an individual or group format. The focus of applied relaxation for panic disorder (MS) is helping the patient to identify situations in which panic is likely and to raise awareness of panic cues. Patients are then trained in the skill of progressive muscle relaxation where they are taught to relax quickly while in increasingly stressful situations.

Posttraumatic Stress Disorder

Prolonged exposure for PTSD (SS) is a specific cognitive behavioral approach for PTSD that includes education regarding common reactions to trauma and PTSD, breathing

retraining (for relaxation), repeated recounting and recording of trauma memory(ies) during therapy sessions, and homework assignments that include listening to the recorded trauma account daily and engaging in *in vivo* exposure (confronting trauma-related, real-world situations that are objectively safe yet have been avoided previously due to trauma-related fear). This treatment typically takes between 10 and 16 sessions. Cognitive processing therapy (CPT) for PTSD (SS) involves psychoeducation, written homework assignments, and a Socratic style of exploration during therapy that helps patients to examine their beliefs about self, others, and the world – especially in the areas of safety, trust, power/control, esteem, and intimacy. Together, the client and therapist identify assimilation, overaccommodation, and accommodation in the client's thoughts and the end goal is to develop beliefs that are balanced and realistic regarding the trauma which, consequently, reduces symptomatology. CPT can be administered in individual or group format and is typically 12 sessions. Present-centered therapy for PTSD (SS) is a supportive intervention that focuses on current life problems as manifestations of PTSD. Psychoeducation about PTSD is provided and the therapist then aids the client in identifying stressors in their everyday life; these general difficulties are then reviewed and discussed in a nondirective, supportive fashion. Stress inoculation therapy for PTSD (MS) teaches patients a variety of coping skills (e.g., breathing exercises, thought stopping, assertiveness skills, deep muscle relaxation, role playing, cognitive restructuring, and/or guided self-dialogue) to help them more effectively manage feelings of anxiety and stress. This approach is often used concurrently with other therapies (e.g., CBT).

Depression

This section will review the individual/group as well as specific couple approaches that have been researched for treating depression.

Individual and/or Group Approaches

CBT for depression (SS) includes interventions such as identifying and modifying negative thinking (e.g., all/nothing or catastrophic thinking and jumping to conclusion) and simultaneously incorporating behavioral interventions like exercise, planning pleasurable activities, etc. It should be noted that behavioral therapy (BT) and cognitive therapy (CT) have been utilized individually and independently (as BT and CT rather than in combination as in CBT), each with strong support for efficacy; hence, a brief review of each will follow. BT/behavioral activation (BA) (SS) is a short-term approach (approximately 12 sessions) that utilizes strategies that focus on increasing the quality and frequency of pleasant activities so that patients can increase their sense of mastery, decrease aversive consequences (e.g., of withdrawal, escape behaviors, and disrupted routines), and improve mood. BA uses graded exercises to systematically increase contact with sources of reward (e.g., pleasant activities), identify barriers to activation, teach problem-solving skills, and improve quality of life. It is believed that no modification of thoughts or insight is necessary for change to occur. Likewise, CT and mindfulness-based cognitive therapy (MBCT) (SS) focus almost solely on awareness and modification of thoughts for improving depression. CT is a time-limited, problem-focused, structured therapy that emphasizes the identifying, monitoring, recording, and modification of maladaptive thoughts and beliefs (e.g., catastrophic thinking, all/nothing thinking, emotional reasoning, jumping to conclusions, and personalization); this challenging and altering of unhelpful cognitions and beliefs is often called cognitive restructuring. Problem solving and development of adaptive coping skills is also a frequent focus. CT for depression can be delivered in both group and individual formats and is typically 14–16 sessions in length. MBCT combines CT techniques with mindfulness meditation. In mindfulness meditation, patients learn to observe, recognize, and change their relationship with negative thought processes. Mindfulness promotes acceptance, nonjudgmentalness, and balanced awareness of self that reduces relapse risk in depression and also often leads to various other medical and psychological benefits. In interpersonal psychotherapy (IPT) for depression (SS), it is proposed that, as psychiatric difficulties most often occur within an interpersonal/social context, teaching patients to identify and understand the relationship between the onset and fluctuation of symptoms and interpersonal problems is essential. Specific interpersonal domains include grief, role transitions, interpersonal role disputes, and interpersonal deficits. The therapist (using techniques that often include clarification, encouragement of affect, communication analysis, and supportive listening) helps to motivate the patient to work toward change in the area of interpersonal difficulties, which, consequently, alleviates symptoms. This treatment is typically 12–16 sessions and can be delivered in both individual and group formats. Problem-solving therapy (PST) (SS) teaches patients to more successfully generate solutions for problems (such as the pursuit of goals or resolution of interpersonal conflicts). PST is a short-term therapy that typically runs between 4 and 16 sessions that can be provided in individual or group formats. Self-management/self-control (SS) is a 10-session program based on Kanfer's (1970) model of self-control that can be delivered in group or individual therapy. Homework assignments, didactic presentations, and instructional exercises are utilized to teach skills and concepts to help patients reduce self-punishment, unrealistic self-evaluative standards, and inaccurate overresponsibility for negative events and to increase self-reinforcement and awareness. Cognitive behavioral analysis system of psychotherapy (SS) is an integrative approach for chronically depressed adults that combines aspects of interpersonal, cognitive, behavioral, and psychodynamic therapies to help patients become more empathetic, alter problematic interpersonal dynamics, and heal from trauma using three primary techniques (situational analysis – raising patient awareness of interpersonal impact on others and altering problematic behaviors; interpersonal discrimination exercises – comparing/contrasting traumatic and healthy relationships to differentiate and allow for more informed decisions; and behavioral skills training/rehearsal – e.g., assertiveness training). ACT for depression (MS) is a behaviorally based intervention that focuses on acceptance, rather than avoidance, of internal experience related to depression (typically unwanted emotions, depression-oriented thoughts, unwelcome memories, and/or bodily sensations) by using defusion and mindfulness techniques so that the patients can increase their activity and ability to engage in behaviors that are meaningful and allow them to move forward in valued directions. ACT also has empirical support for being effective with other difficulties that can contribute to depression such as chronic pain, OCD, and

psychosis. Emotion-focused therapy (EFT) (MS) is built on a process-experiential approach designed to facilitate patient identification, utilization, and processing of emotion in the environment of a safe, secure, therapeutic relationship. Three specific phases (emotion awareness, emotion regulation, and emotion utilization/transformation) assist patients to increase awareness of emotions, deepen emotional experiences, recognize/regulate unhealthy emotional responses, and utilize healthy emotions to guide behavior. This approach is typically delivered in an individual format and is 16–20 sessions in length. Rational emotive behavioral therapy (MS) is a type of short-term (i.e., 14–20 sessions), present-focused CBT that focuses almost exclusively on efforts to diminish demanding beliefs (e.g., 'musts,' 'shoulds,' and 'oughts'), reduce secondary problems (e.g., depressive feelings about depression), and promote unconditional self-acceptance. The A-B-C model (action, belief, and consequence) and other variants are also often utilized to identify problematic beliefs to focus on in therapy. It can be delivered in either individual or group formats. Short-term psychodynamic therapy (MS) is a brief dynamic therapy aimed at increasing the patient's insight and awareness of core conflictual relational themes and problematic patterns that contribute to depression. Other common foci might include expressions of emotion and identification of how current functioning is impacted by past experiences. This approach typically takes place individually in 16–20 sessions.

Couple Therapy Approaches for Depression

Behavioral couples therapy (BCT) (MS) is designed for couples wherein one of the partners is depressed. BCT focuses on problem solving, communication, and the exchanges that occur between partners to improve relationship functioning, support, and to decrease conflict, which, consequently, decrease depressive symptoms in the affected partner. This treatment typically takes between 12 and 20 couple sessions. Emotionally focused couples therapy (EFCT) (MS) focuses on the here-and-now construction of the emotional experience and interpersonal patterns of interactions of a distressed couple. Psychoeducation regarding adult love and bonding processes is provided and the EFCT therapist aids the couple in reshaping interactions so that a more secure attachment can be formed. Through reorganizing interactions, reprocessing about experience, and increasing safety, trust, and contact, the couple is able to create a more secure bond that benefits both. Treatment typically comprises 8–20 couple sessions.

Eating Disorders and Obesity

Empirically supported interventions for anorexia nervosa, bulimia nervosa, binge eating disorder, and obesity have been proffered, several of which include family components.

Anorexia Nervosa

Family-based treatment (FBT) (SS) for anorexia nervosa is a three-phase treatment that may follow a brief stay in an inpatient unit (if medical concerns are present) or can begin on an outpatient basis. In the first phase, the parents collaborate with the therapist to assume responsibility for weight restoration and nutritional rehabilitation (while the adolescent maintains autonomy in other areas of life as developmentally appropriate). In the second phase, (after acute starvation is reversed), control over eating is returned to the adolescent. The third phase includes addressing issues of family structure, normal adolescent development, and termination. This approach typically takes place in 20 sessions over the course of 12 months. CBT for anorexia nervosa (MS) is a post-hospitalization relapse intervention designed to prevent a return of symptoms following the completion of inpatient treatment and subsequent weight gain. It is typically conducted in individual sessions that occur over 1 year wherein behavioral strategies (regular pattern of eating, systematic exposure to 'forbidden' foods) and attending to cognitive features of the disorder (disturbances in perception of weight/shape, motivation for changing) are utilized in order to accomplish the explicit goals of achieving and maintaining a healthy weight.

Bulimia Nervosa

CBT for bulimia nervosa (SS) is a present-centered treatment that targets the current symptom cycle rather than attempting to determine etiology. It includes three phases of treatment over approximately 20 weekly sessions. In the first phase, psychoeducational information regarding adverse physiological consequences of extreme dieting, bingeing, purging, and weight is shared and the aim is to establish a regular pattern of eating as well as developing an appropriate schedule for monitoring weight. Phase two is designed to reducing diet behaviors as well as weight/shape concerns and identification of relapse warning signs is also a focus. In the third phase, the focal point is maintenance of progress and relapse prevention. CBT is utilized throughout the phases to disrupt variables (e.g., cognitive distortions) that perpetuate the binge–purge cycle and then to achieve and maintain abstinence from bingeing and purging behaviors. IPT has also been modified for treating bulimia nervosa (SS). While the connection between bulimia nervosa and interpersonal difficulties is identified at the beginning of therapy, the symptoms of bulimia nervosa are never an explicit focus. Rather, an interpersonal problem domain is identified (grief, role transitions, interpersonal role disputes, and interpersonal deficits) and interpersonal precipitants are identified. The focus then shifts to facilitating change in the interpersonal realm with the third phase focused on progress made and relapse prevention. Treatment typically takes 20 weekly sessions and can be delivered in individual or group format. While strong research support for IPT for bulimia nervosa exists, it has been noted that these gains tend to be made more slowly than in CBT. FBT for bulimia nervosa (MS) was adapted from FBT for anorexia nervosa and, consequently, also has three phases of treatment. This treatment typically encompasses 20 sessions over 6 months.

Binge Eating Disorder

CBT (SS) for binge eating disorder is a three-phase treatment that primarily focuses on the maladaptive eating patterns and feelings of distress and loss of control that precipitate binge eating behaviors. In the first phase, the approach is dependent upon whether the individual is obese or not; if obesity is an issue the aim is to persuade the patient to prioritize termination of binge eating over immediate weight loss so that an appropriate weight monitoring and eating schedule can be established (if the person is not obese this step is not necessary). Psychoeducational information regarding nutrition is supplied and a regular

exercise program is encouraged. Phase two encompasses identification of problematic beliefs ('food addiction,' self-esteem based solely on appearance, etc.) and a goal of reducing weight/shape concerns and increasing the definition of self-worth ensues. The last phase is devoted to maintenance and relapse prevention planning. CBT techniques are used throughout and aimed at the disruption of and cessation from factors (thoughts, emotions, behaviors, etc.) that perpetuate binge eating. This treatment typically takes place over approximately 20 weekly sessions in either individual or group formats. IPT has also been adapted for binge eating disorder (SS). Typically, IPT for binge eating disorder takes place over 20 weekly sessions in a group or individual format.

Obesity and Pediatric Overweight

Behavioral weight loss (BWL) treatment (SS) is a short-term approach aimed at establishing new behavioral patterns to achieve acute weight loss and maintain weight reductions attained. The LEARN (lifestyle, exercise, attitudes, relationships, and nutrition) Program is a 12-session holistic approach for adults that encourages small lifestyle changes that, along with reasonable weight goals and moderation in food choices, yields weight loss. Adaptations of BWL for children have also been developed.

The Negative Effects of Psychotherapy

While research overwhelmingly suggests that psychotherapy facilitates reductions in symptomatology, improves everyday functioning, and results in appreciable gains and clinically meaningful change, contrary to the intent of psychotherapy, research also shows that there are some clients who actually worsen during the course of treatment. Similar to client improvement, research shows the phenomenon of deterioration to be equivalent across theoretical orientations (Lambert et al., 1977). Likewise, negative outcomes have been observed across all client populations, treatment interventions, and family and group therapies. In fact, research shows a relatively consistent proportion of adults (5–10%) and an alarmingly high portion of children (14–24%) deteriorate when participating in treatment (Lambert, 2013; Warren et al., 2010). While therapy factors (inadequate conceptualization, applying treatments that do not cover the full range of patient problems, unsuitable treatment) may be liable, this finding does not mean that all instances of worsening are attributable to therapy itself as a myriad of other factors may be present.

Instances that are independent from treatment can occur such as an inevitable negative life event (e.g., loss of loved one and medical condition) or a progressive decline that is inescapable (such as dementia). Unfortunately, as mentioned prior, severity of mental illness alone is predictive of unsuccessful outcome. Higher levels of interpersonal problems and a higher degree of seriousness in presenting problems also predict poor results. In addition, certain diagnoses and symptoms (e.g., borderline personality disorder, OCD, psychotic, schizophrenic, and bipolar) seem less amenable to psychotherapeutic intervention. Client, setting, and therapist factors related directly to treatment might also help account for treatment failure (e.g., the inability of therapists to repair ruptures in the therapeutic alliance; Muran and Barber, 2006).

Just as some client characteristics help maximize gains, other client factors such as poor motivation, sporadic attendance, hostility, resistance to therapist suggestions and prescriptions, complicated problems, negative expectations of treatment, dysfunctional relationship dynamics or environment, and/or unreported problems/issues predict poor outcomes (Bohart and Wade, 2013). The setting in which the client is seen also seems to play an important role in whether clients improve or deteriorate (Warren et al., 2010). In general, about two-thirds of adults who participate in therapy in a randomized controlled trial (where client comorbidity is minimized, therapists are experts in the approach, manuals standardize treatment, etc.) have a positive outcome in approximately 14 sessions and about 30% of patients show no benefit or worsen; in routine practice settings (e.g., community health centers and employee assistance programs) research shows that clients do not fare as well as only about one-third demonstrated improvement or recovery, more than 50% did not respond, and an average of 8% deteriorated (Hansen et al., 2002).

Lastly, specific therapist behaviors have also been found to lead to treatment failure. Clinician competence and mastery vary and, not surprisingly, some therapists respond better to challenging patient presentations than others. Studies focused on deterioration have found lack of empathy, underestimation of the severity of client concerns, and/or overestimation of client progress to be detrimental; multiple studies also underscore the destructiveness of therapist negative reactions toward the client that reflect irritation, hostility, and disappointment (Mohr, 1995; Henry et al., 1986).

Fortunately, innovative resources have been developed to help reduce rates of deterioration in psychotherapy. Routine monitoring of outcome measures taken at each contact with the client can provide real-time clinically relevant feedback to the therapist that provides a benchmark for the client's progress in therapy (Boswell et al., 2013). One such resource has created software that employs score-specific algorithms that track progress, detect 'off-track cases,' sends alarm signals to the therapist for those predicted to have a negative outcome (e.g., deterioration and premature termination) so that ameliorative action can be taken; the result of such an intervention resulted in reducing deterioration rates from 20 to 13%. When clinical support tools were incorporated that helped to identify possible causes of negative response and provide possible solutions/ideas for corrective interventions, the deterioration rate dropped to approximately 8% while positive outcomes doubled (Lambert, 2010; Shimokawa et al., 2010).

Conclusion

Decades of research compellingly demonstrate that when aligned with a wise, skillful, sound provider, clients entering therapy can expect to reduce symptoms, accelerate natural healing processes, improve life functioning, and learn additional methods and coping strategies to present return of their symptomatology. Those who seek therapy consistently have better outcomes than those who do not receive treatment (or are on a wait list) and a broad range of therapies have be shown to assist patients make changes that are both statistically and

clinically meaningful in relatively short periods of time. For many clinical disorders, generally one-half of all patients return to normal functioning in 10–20 sessions. An additional 25% of patients experience substantial improvement when dosage levels are increased to 30–50 sessions. With the exception of disorders that tend to recur (e.g., addiction disorders and personality disorders), the benefits from treatment appear to be durable as the results of follow-up studies suggest that the effects of psychotherapy endure for at least 1–2 years subsequent to treatment. These results seem at least partially attributable to the emphasis and efforts that psychotherapists make to help clients make enduring (as opposed to temporary) changes through consolidating gains, strengthening coping skills, and safety planning toward the end of therapy.

Unfortunately, not all patients experience beneficial effects of treatment and investigation of factors that contribute to both positive and negative change are ongoing. One confirmed way to monitor the efficacy of treatment and improve client success is to implement ongoing monitoring of client mental health functioning with alarm signals and problem-solving tools for off-track clients (Shimokawa et al., 2010).

Psychological Treatments Delivered Nontraditionally

Marion K Jacobs, University of California, Los Angeles, CA, USA
Jim Rue, Laguna Beach, CA, USA

Abstract

Psychological treatment traditionally implied an ongoing, face-to-face relationship between a patient and a trained mental health professional. However, over the last 35 years, cultural shifts, new technologies, and a reshaped health care delivery system have resulted in the emergence of new types and formats of psychological assistance. Nontraditional treatments and formats now include: self-help/mutual support groups; computerized programs; radio and TV talk shows; Internet offerings via blogs, chat rooms, instant messaging, bulletin boards, e-mail, and social media outlets; and self-help books, CDs, and DVDs. Not only mental health professionals but paraprofessionals and nonprofessionals (widely varying in their qualifications to offer such help) create these materials and market these services.

As delivery formats have extended to new forms, so has the nature of the contact between user and provider. While some treatments are still face to face, newer alternatives are direct but electronic communications (not necessarily in real time) through telephone, TV, radio, web sites, or e-mail. The connection between the helper and the person receiving help is further attenuated through indirect interactions, for example, using interactive computerized programs. Finally, when printed materials or materials offered on CDs and DVDs are used on a self-help basis, there is no two-way connection between those offering and those receiving psychological treatments.

The varieties and uses of nontraditionally delivered psychological assistance, both as adjuncts to traditional treatment and as the sole form of intervention, have burgeoned in the last 10 years, spurred by advances in the field of Information Technology (IT). A notable example is the 'virtual environment' technology that provides users with the opportunity to learn and practice new behaviors under conditions mimicking the real-life experience. Another is e-mobile applications ('apps') downloaded to mobile phones, tablets, and e-readers. Using apps for guidance, help seekers can practice skill development at their convenience, as often as they like. If a treatment provider is directly delivering services to that user, treatment-oriented apps provide an additional opportunity for the provider to monitor the user's guided behavioral practice between sessions. Given the pace of technological innovation, this trend seems likely to accelerate. However, priority needs to be given to researching the safety and effectiveness of these new mental health interventions.

An Evolving Picture

The term psychotherapy traditionally connoted an interactive, face-to-face process in which a trained mental health professional attempts to help a client, or group of clients, effect personal change. Authority and responsibility for facilitating such change reside with the professional, whose presence and expertise are deemed necessary to guide and control the meetings in accordance with sound clinical and ethical practices.

Since the 1970s, an array of interventions for delivering psychological assistance has come into being that deviates significantly from the traditional psychotherapy format. Much of this changing landscape is based on developments in IT, meaning the use of computers and telecommunication equipment, including TV, telephones, and tablets, to store, retrieve, transmit, and manipulate data. In general, these new formats enjoy widespread popularity among the general public and their use is less directly controlled by a mental health professional. Such alternative psychological interventions include radio and TV shows dispensing psychological advice, (sometimes seemingly more for purposes of entertainment); interactive software for addressing a wide variety of personal problems and providing practice exercises; self-help books, CDs, and DVDs; and mutual support groups that arose after TV talk shows began focusing on problems such as sexual abuse, alcoholism, and other topics previously not openly discussed. More recently, the spate of cyberspace offerings includes self-help guides, single session e-mail and bulletin board advice, ongoing e-mail counseling, real-time chat groups, web telephony, and videoconferencing.

An emerging technological development is the use of 'virtual environments' to deliver psychological treatment. These are computer-controlled, interactive experiences, some using avatars (online proxies) that propel people into simulated three-dimensional worlds, which appear and feel emotionally close to the real-life experience of being in such a setting. Exposure to problematic situations in these virtual environments allows users to experience emotions in a controlled way and practice constructive emotional and behavioral responses in a realistic yet safe setting, thus developing the confidence to deal with the problem effectively in the real world. Virtual environments may be under the guidance of a therapist. For an example, a patient might use realistic flight simulator software in the therapist's office to help overcome a fear of flying. Therapeutic programs can also be utilized solely on one's own, for example, employing avatars at the popular Second Life (www.secondlife.com). Early research findings on the efficacy of virtual approaches to treatment appear promising (DeAngelis, 2012). Virtual reality technology offers important opportunities to bolster the power of psychological treatment approaches. This newer capability of simulating a total reality is a powerful advance in creating the necessary conditions for personal change.

Just as virtual reality represents a nontraditional approach to psychological treatment, so too does the widespread use of applications ('apps') on mobile devices. Many helpful therapeutic programs and other resources are now available on smartphones, tablets, and e-readers, allowing unlimited access, at the convenience of the user. For example, Psychological First Aid (PFA) Mobile is a mobile phone application for mental health providers and other response workers who provide PFA shortly after disasters and emergencies. It represents a collaborative effort among four US government agencies. For research on an app for therapy via cell phone, see Morris et al. (2010). Indeed, as it relates to psychological interventions, easy, low cost, around-the-clock availability of mental health apps, whether in conjunction with other treatments (Morris et al., 2010), or strictly on their own, is an important breakthrough, part of what some call a 'mobility revolution.'

There are promising early research results about the efficacy of Internet-delivered treatments (e.g., Cuijpers et al., 2010; Hester et al., 2011; Andrews et al., 2010). More research is needed to evaluate their effectiveness and safety. That said, there is no denying that convenient, lower cost formats are appealing. They also make psychological aid available to people who would not, or could not, utilize more traditional psychotherapies. Included here are the homebound people living in remote areas, those who shun psychotherapy as stigmatizing and people who insist on total privacy and independence when dealing with their psychological issues.

Social Climate and the Rise of New Forms of Psychological Treatment

Social climate is another important factor giving rise to these new models of psychological assistance. As compared to traditional forms of psychotherapy, nontraditional approaches tend to involve less direct professional contact and control, even when the treatment is designed or delivered by a mental health professional. This shifts away from strictly professional delivery of mental health services, at least as it has evolved in the United States of America, reflects an intersection of several cultural developments.

At a broad societal level, in the United States of America, considerable value has been placed on empowering the individual, as opposed to almost total reliance in the past on institutions and professionals for information, support, and assistance. This has a lot to do with the ease of using search engines, but it also stems from a post-Watergate, post-Vietnam eroding of American public's confidence in the corporate world, government, the medical establishment, and other institutions. Activist movements (civil rights and minorities, women, consumers, gays and lesbians, and others), further reinforce values promoting personal entitlement and empowerment as well as greater acceptance of cultural diversity.

Today, people have more information and demand greater involvement and control over health care decisions than they did in the past. Advances in communications support that demand. For example, before the 1980s, personal issues such as alcohol and drug abuse, child molestation, family violence, sexual orientation, bulimia and anorexia, cancer, sexually transmitted diseases, Alzheimer's disease, fetal alcohol syndrome, mental illness, and posttraumatic stress disorder among Vietnam veterans, were topics rarely spoken of in public. Talk shows of the early 1980s played an important role in bringing such closeted issues into open discussion as people became increasingly sophisticated about such problems. Learning about the mind–body connection and the potentially damaging effects of stress on mental and physical health helped set the stage for receptivity to new delivery formats that have made psychological aid less costly and more widely accessible.

New models meet a clear-cut public need. Scientific surveys of the prevalence and incidence of mental health problems make it clear that we do not have, and probably never will have, a sufficient number of trained mental health professionals to deliver traditional services to all those needing them. What is more, the need for psychological services continues to grow, fed by a continuing population growth and density. That growth is further fed by advances in medical science that increase the survival rates of people with serious chronic medical conditions, putting added stresses on those patients and their families (Kazdin and Rabbitt, 2013). At this writing, the stress caused by the recent and protracted economic recession also creates an increased need for mental health services (Burgard, 2012).

There is increasing awareness at governmental and scientific levels that widespread mental health problems exact huge social and economic costs to a nation. Further, a growing body of research from the field of Psychoneuroimmunology shows that psychological stressors negatively impact the immune system, general health, and overall functioning. The same body of research also shows that social support and the opportunity to constructively discuss problems can positively affect health, enhance the quality of life, and, by strengthening the immune system, in some instances even promote longevity by reducing the incidence of life-threatening illnesses (Kiecolt-Glaser, 2009). Although Western medicine claims one of its missions is promoting health and preventing the occurrence or the worsening of disease, it often fails to employ what is known about the mind–body connection and its impact on health and well-being.

Further, under managed care, doctors and nurses, traditionally an important source of informal psychological assistance, now have less time to spend with their patients than in the past. The paradoxical result is a public increasingly aware of the connection between stress and illness and desirous of help, while affordable psychological services are less accessible than in the past. Psychologists Alan Kazdin and Sarah Rabbitt (2013) see this lack of services as very detrimental to individuals, families, and even nations. They argue for the necessity of invoking new models of service delivery that are capable of reaching wider swaths of people at lower costs. The models they propose for mental health care delivery derive from practices commonly used today in business, public health, and medicine.

To summarize, four factors stand out as particularly influential in promoting nontraditional psychological treatments: (1) the growing public awareness and desire for help while the availability of affordable professional psychotherapy is decreasing, (2) the value placed on personal entitlement and empowerment in today's society, (3) an ongoing revolution in

IT and its electronic forms of communication, including often via mobile devices, and (4) the rapid dissemination of information by today's highly competitive mass media businesses. Given these forces, it is not surprising that enterprising people continue to seek alternative, accessible, and less costly (although sometimes financially profitable) ways of delivering psychological treatments.

One example of a break from traditional psychotherapy began in the late 1970s, as the number and type of self-help/mutual support groups multiplied rapidly (Goodman and Jacobs, 1994). Some groups had existed for decades, the best known being Alcoholics Anonymous and Recovery, Inc. Suddenly groups sprang up for almost every conceivable personal problem from substance abuse, to parenting concerns; to domestic violence; to transitions such as divorce, retirement, and bereavement; to lifestyle issues like sexual orientation, transvestitism, and open marriage. Groups also came into being for almost every disease listed by the World Health Organization. Millions of people joined them. Although some groups utilize professional leaders or professionally developed ideas, many have little or no professional input. Sociologist Frank Reissman (Gartner and Reissman, 1985) terms the heart of the self-help group movement the 'helper-therapy' principle – the idea that when people suffering from a common problem come together for mutual support, they not only receive help from others, particularly from those more experienced in coping with the problem, but also give help, and in so doing are themselves strengthened and empowered. In the 1980s, many health professionals held negative views about self-help groups, asserting that lay people operating on their own were likely to harm each other by dispensing bad advice. While this remains a concern, the less openly discussed issue was their concerns over loss of professional control and income. In time, professionals have become more supportive of self-help groups as an adjunct to traditional treatment and as a useful, member-governed intervention in its own right. Today, many professionals are directly involved with groups in a variety of roles such as consultants, researchers, leaders, coleaders with group members, and even as participants who share the group's common concern.

The relatively unregulated nature of the various forms of nontraditional psychological treatment offered to the lay public continues to raise concerns about their safety, quality, and effectiveness. Research into the use of paraprofessionals vs professionals, self-help books vs therapist-delivered services, and computer-assisted vs therapist-delivered treatment generally shows these alternatives similar in their effectiveness to professionally delivered psychotherapy (Christensen and Jacobson, 1994; Patel et al., 2011). But, some formats have never been studied. Even among those that have, many important questions remain. For example, are some nontraditional formats more appropriate for certain types of people, or certain types or levels of severity of problem? Further, the relatively unregulated nature of the Internet leaves the door open to poor quality offerings, untested claims, and even outright deception from those designing and offering psychological assistance. In the interest of assuring quality services for the public, priority needs to be given to educating Internet users and service providers, and researching appropriate standards.

Psychological Treatments, Empirically Supported

William C Sanderson, Hofstra University, Hempstead, NY, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The last decade has witnessed efforts to bring findings from clinical research on psychosocial interventions into everyday clinical practice. These efforts have sought to identify treatments for specific diagnoses that have shown efficacy through empirical study. The identified therapies have been termed empirically supported treatments. In this article, the forces that are driving the move toward empirically supported treatments will be discussed. In addition, the specific criteria used to determine empirically supported treatments will be presented and links to an up-to-date list of these treatments will be provided. Finally, several prominent controversies and criticisms of the move toward empirically supported treatments will be reviewed.

The scientific study of psychological treatments has a long history in clinical psychology. The interest in using scientific evidence to inform clinical practice is best characterized by Paul's (1967) quote: "What treatment, by whom, is most effective for this individual with that specific problem, under which set of circumstances?" (p. 111). On a practical level, identifying empirically supported treatments (ESTs) for specific conditions allows service providers to utilize the most effective treatment and as a result, improve outcomes for clients.

Recently, there has been a renewed interest – with urgency – in identifying empirically supported psychological treatments. This is particularly a function of changes in the US health care system, set in motion during the mid-1990s and continuing to evolve, which has increased the need for accountability in the treatments that are provided. Two primary forces are driving these changes: (1) the increasing penetration of managed care and other types of cost-conscious medical insurance plans, and (2) the development and proliferation of clinical-practice guidelines. Essentially, managed care and practice guidelines ask the same question: "Does a treatment work, and if so, is it cost-effective?" Although these forces are influencing every area of health care, the current article will discuss their specific impact on the practice of psychotherapy.

Managed Care

More than any previous event, managed care organizations (or any other system monitoring the utilization and cost of services such as health maintenance organizations, capitated contracts with providers, etc.) are reshaping the practice of psychotherapy (*see* Managed Care and Psychotherapy in the United States). In the traditional fee-for-service model, decisions about the cost and length of treatment were primarily a function of choices made by the doctor and patient. The allocation of resources (i.e., cost of psychotherapy) was of little concern to the clinician. In fact, the fee-for-service model encourages the provision of service, as more service creates more income. However, in response to the increased costs of psychotherapy, and in particular to the perceived 'endless' nature of psychotherapy, managed care organizations are pressuring clinicians to allocate decreasing (less than usual) amounts of service. While to date, the focus of managed care organizations' cost cutting has been almost entirely devoted to limiting the number of sessions a patient receives, ultimately, in order to compete, managed care organizations will have to focus on the quality and efficacy of the psychotherapeutic interventions as well. Managed care organizations are clearly motivated to cut costs. However, they must also satisfy the consumer (i.e., patient), and payer (e.g., employer providing health benefits) and therefore they will have to balance cost-cutting with patient outcome. Simply reducing the length of care will not accomplish this goal, because many, and perhaps the majority, of psychotherapists are trained in 'long-term' therapeutic interventions, which by nature require more sessions than managed care organizations are willing to allocate. Simply reducing the length of therapies devised to take place over a longer period of time is likely to result in ineffective outcomes, leading both to consumer dissatisfaction and increased costs down the road as the severity of the disorder may increase, becoming less responsive to treatment. Thus, concern for the effectiveness of interventions will eventually temper the managed care organizations' focus on economy. Ultimately, managed care organizations will be interested in clinicians providing the "optimal intervention…the least extensive, intensive, intrusive, and costly intervention capable of successfully addressing the presenting problem" (Bennett, 1992: p. 203).

Practice Guidelines

A second force that is having a significant impact on the practice of psychotherapy is the establishment of clinical practice guidelines and treatment consensus statements. As noted by Smith and Hamilton (1994), "Guidelines are now being developed because there is a perception that inappropriate medical care is sometimes provided and that such inappropriate care has both health and economic consequences" (p. 42). It is well known that in all medical fields there is significant variability in treatments delivered to patients with various illnesses. Patients are not necessarily receiving the most effective treatment. Consequently, in order

 http://dx.doi.org/10.1016/B978-0-08-097086-8.21079-9

to ensure that patients uniformly receive the optimal intervention – whether it be a type of medication, surgical procedure, or psychotherapeutic intervention – clinical practice guidelines are being developed. For the most part, the development of practice guidelines relies on systematically evaluating scientific and clinical inputs.

One organization developing practice guidelines is the federal Agency for Healthcare Policy and Research (AHCPR). In order to create impeccable guidelines, only treatments with documented efficacy from randomized, controlled trials are considered. Therefore, for an intervention to be included as a first-line treatment, research evidence attesting its efficacy must be available. Without this evidence, one cannot conclude if a treatment is effective or ineffective, or make judgments about its relative efficacy compared with other available treatments.

The recommendations of the clinical practice guidelines are quite clear. Consider the wording from the AHCPR guideline for depression (Depression Guideline Panel, 1993). When psychotherapy is going to be selected as the sole treatment, the guideline states "Psychotherapy should generally be time-limited, focused on current problems, and aimed at symptom resolution rather than personality change as the initial target. Since it has not been established that all forms of psychotherapy are equally effective in major depressive disorders, if one is chosen as the sole treatment, it should have been studied in randomized, controlled trials" (Depression Guideline Panel, 1993: p. 84). In addition to endorsing specific treatments for depression that has sufficient empirical evidence (e.g., cognitive, behavioral, interpersonal), the report goes on to state "Long-term therapies are not currently indicated as first-line acute phase treatments" (p. 84).

Along the same lines as treatment guidelines, consensus statements are likely to carry significant weight in determining the efficacy of treatments. For example, in 1991 a consensus development conference on the 'Treatment of Panic Disorder' was held, sponsored by the National Institute of Mental Health. As was true in the process of developing the AHCPR treatment guidelines, the merits of various treatments was determined by the available scientific evidence. The format of the conference was to let 'each camp put its best data forward' and the panelists would evaluate and weigh the evidence to formulate a consensus statement (Wolfe and Maser, 1994). As in the case of treatment guidelines, specific treatments were judged to be effective for panic disorder including several pharmacological compounds and cognitive behavioral psychotherapy (cf Panic Consensus Statement published in Wolfe and Maser, 1994). Once again, as is true of treatment guidelines, the wording of the Panic Consensus Statement on the use of treatments not supported by empirical evidence, whether they be psychological or pharmacological, is quite clear, "One risk of maintaining individuals in nonvalidated treatments of panic disorder is that misplaced confidence in the therapy's potential effectiveness may preclude application of more effective treatment." The statement spells out a specific concern about the use of psychotherapies without demonstrated effectiveness for panic disorder, "The nature of the therapeutic relationship makes it difficult for the patient to seek additional or alternate treatment."

As clinical guidelines and treatment consensus statements continue to emerge for a wide array of emotional disorders, they will have further impact on the way clinicians practice psychotherapy. In effect, these documents set standards of care, which if ignored, leave the clinician both ethically and legally vulnerable. Health insurance companies and managed care plans are now providing their practitioners with copies of these guidelines and asking that they be followed. The implications are clear: failure to provide an EST from these guidelines, where one exists, may constitute malpractice in the eyes of the payer. For example, a number of states have passed, or are in the process of passing, legislation that gives these guidelines the 'force of law' by protecting clinicians who follow the guidelines from malpractice litigation (Barlow and Barlow, 1995).

Identifying Empirically Supported Treatments

Recognizing the lack of utilization of ESTs and considering the trends noted above, the Society of Clinical Psychology (Division 12 of the American Psychological Association) established a task force to identify, promote, and assist in the dissemination of ESTs. The original Task Force on Promotion and Dissemination of Psychological Procedures (presently named the Committee on Science and Practice; CSP) was created by David H. Barlow, then President of the Society. The CSP is now a standing committee in the Society of Clinical Psychology, and the work will continue into the future (all reports from this committee are available at http://www.div12.org/psychological-treatments/).

The primary mission of the original task force was to define criteria to determine whether treatments qualified as ESTs. The following criteria were established (Chambless et al., 1998). For treatments to be considered by the task force, research must have been conducted with treatment manuals. This requirement was set because treatment manuals make for better research design, and the use of a treatment manual allows readers to know what specific procedures have been supported. For example, although many interventions fall under the rubric of behavior therapy (e.g., exposure, relaxation training, cognitive restructuring), only exposure and response prevention have been demonstrated as efficacious for obsessive-compulsive disorder. Stating that behavior therapy is effective for obsessive-compulsive disorder does not allow the reader to know what specific strategies were tested and how they were applied. Use of the treatment manual solves this dilemma.

As for whether or not the treatment qualifies as an EST, the task force distinguishes between two levels of EST – 'well established' and 'probably efficacious.' EST status is determined by the results from group design and single-case design studies. With regard to group design studies, to qualify as a well established treatment, at least two studies conducted by different investigators must be presented as supporting studies. The following criteria must be satisfied for qualification as a supporting study: (1a) treatment is superior to pill placebo or psychological placebo, or (1b) treatment is equivalent to an already established treatment; (2) a treatment manual was used in the study; (3) characteristics of the client sample must be

clearly specified. A treatment may not meet the criteria for being 'well established' but may still satisfy the less conservative criteria for a 'probably efficacious' treatment if (1) two studies show that the treatment is more effective than a waiting list control group, or (2) only one supporting study exists, or if more than one exists, all were conducted by the same investigator. (For details concerning the definition of EST, including use of single subject designs and resolution of conflicting data, the reader is directed to the task force report itself located at http://www.div12.org/psychological-treatments/.)

Beginning in 2007 an online version of the list of ESTs was developed, and since it is updated regularly, it represents the latest list ESTs: http://www.div12.org/PsychologicalTreatments/index.html. (It is important to note that it is not assumed that treatments without empirical evidence supporting them are ineffective, but instead, that in the absence of scientific data, no conclusion has been drawn about their efficacy or lack thereof.)

The movement toward ESTs has not been welcomed by everyone within our profession, and indeed, several authors have raised important concerns and criticisms (e.g., Garfield, 1998; Kovacs, 1995; Nathan, 1998) regarding the identification of 'validated' therapies. Although space does not permit a discussion of the specific issues here, in fact, the CSP agrees that there are difficulties and risks in establishing so-called psychotherapy guidelines – or any treatment guidelines for that matter (cf Pincus 1994 concerning the development of psychiatry guidelines) – yet the CSP and other professional organizations believe that the benefits clearly outweigh the risks (Pincus, 1994; Sanderson, 1995), and thus, will continue the work outlined above (cf Weisz et al., 2000 for a discussion of the future directions of the CSP).

Why Is There Controversy over ESTs?

In principle, most psychologists are likely to agree on the necessity of providing empirical support for the treatment interventions they use. It is also reasonable to assume that consumers expect to receive a mental health treatment whose effectiveness has been proven, when such a treatment is available. Therefore, one would expect clinicians to embrace ESTs. However, psychologists are split on the evidence-based practice (EBP) movement and it has been a hotly debated issue in the literature as well as among practicing psychologists today (e.g., Garfield, 1998; Kovacs, 1995; Nathan, 1998). The controversies over the use of ESTs are briefly summarized below:

First, many clinicians claim that EBPs essentially favor cognitive-behavioral therapies because these represent standardized treatments that can be tested more readily in controlled clinical trials. As a result, they believe that viable alternative treatments (e.g., psychodynamic therapy), which cannot be as easily standardized, will fail to measure up to the EBP criteria, even though they may be effective in clinical practice. Secondly, it has been argued that most studies supportive of EBPs fail to capture the complexity and uniqueness of patients seen in 'actual' practice. Consequently, these clinicians question the applicability of these manualized treatments to patients seen in the community. Along the same lines, thirdly, while ESTs clearly work in the controlled research environment, data are lacking on how well they generalize to real-world settings such as hospitals, community mental health clinics, private practice offices, etc. Since these settings usually differ substantially from clinical research centers (with regard to therapist skill and patient characteristics), many argue that one cannot assume ESTs generalize to real-world clinical settings. Finally, many clinicians have a negative reaction to being 'told what to do' by researchers who generate these data. This is part of an ongoing tension between scientists and practitioners as to who 'knows best' about treatment decisions – those who generate the research findings or those who provide clinical treatment in actual practice.

Of course, many of these questions can be answered by empirical research, which must ultimately provide the answers in order to allow clinicians in the field to fully embrace ESTs. Although space does not permit a discussion of the specific issues here, in fact, there are difficulties and risks in establishing so-called 'psychotherapy guidelines' – or any treatment guidelines for that matter (cf Pincus, 1994 concerning the development of psychiatry guidelines). However, many believe that the benefits clearly outweigh the risks (e.g., Pincus, 1994; Sanderson, 1995).

Psychological Treatments: Randomized Controlled Trials

William S Agras, Stanford University, Stanford, CA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The evolution of controlled clinical trials for psychological treatments began in the 1930s and became more frequent with the development of behavior therapy following Eysenck's critique of the effectiveness of psychological therapies in 1966. Now there are a number of different experimental designs suitable for the investigation of different questions posed by investigators. Multisite clinical trials are useful because they can recruit larger number of participants with a particular problem in a shorter time than can be accomplished at one site and are more likely to lead to policy change. Issues such as mediators and moderators of outcome, cost-effectiveness, and future developments are also highlighted.

The aim in developing a psychological therapy is to produce an effective treatment that can be used by therapists in many different clinical settings (*see* Evidence-Based Psychotherapy). The development of a psychological treatment begins with observations flowing from the treatment of patients based on a theoretical model of behavior change. The process continues with a series of cases in which the treatment is refined and its initial effectiveness confirmed. At this point, a therapist manual, a detailed account of the therapeutic procedures, is developed enabling training of therapists and allowing others to replicate the treatment. The treatment is then tested in randomized controlled clinical trials. If these trials continue to demonstrate effectiveness with replication by other researchers, a new evidence-based psychotherapy will have been developed. All too often the process ends at this stage with the result that few practitioners actually use the treatment.

The next stage in the development of a psychotherapy is to disseminate the results through publications and workshops. Unfortunately, this rarely results in more widespread use of the treatment, because research has shown that such dissemination does not increase the use of a novel psychotherapy. Hence, it is important to implement the therapy in settings in which it will be used (*see* Implementation Science). Before implementation certain questions need to be considered. First, in what setting or settings are the treatment needed? Second, what is the nature of those settings? Third, are the therapists in those settings interested in using a new evidence-based psychotherapy? Hence, the researcher needs to understand the nature of these settings in which psychotherapy is to be implemented and the needs of therapists in those settings. Moreover, it is important to engage psychotherapists in those settings because they may provide valuable input into changes in the process of therapy that would need to be incorporated into the adapted treatment to fit the needs of their practice. The next step is to adapt the newly developed treatment to fit those settings. For example, if the new psychotherapy was developed as a 20-session treatment but most clinical settings in which it will be used do not deliver more than 8 sessions of psychotherapy to their clients, the original treatment will need to be shortened, adapted, and tested in further randomized controlled trials in these clinical settings to determine if it is efficacious. Unfortunately, this 'ideal process' takes several years, and steps are often skipped or assumed to be unnecessary resulting in the situation commented upon by the Director of the National Institute of Mental Health (Insel, 2009) "We have powerful, empirically-supported psychosocial interventions, but they are not widely available … A serious deficit exists in training for empirically supported psychosocial interventions … Translational research will need to focus not only on 'bench to bedside' but also on 'bedside to practice.'"

The Development of Controlled Clinical Trials in Psychology

Parallel developments in two clinical disciplines, medicine and psychology, beginning in the 1930s, edged both fields toward the use of controlled trials. In an early study spanning both, medicine and psychology (Chappell and Stephenson, 1936), the authors demonstrated that an educational group program resulted in greater improvement and less relapse in a group of peptic ulcer patients than the control group, both groups having received the same medical care. Another study, the Cambridge–Somerville Youth Project, begun in the late 1930s and continuing with a long-term follow-up into the 1950s, was one of the earliest trials of a psychological treatment (Teuber and Powers, 1953). This large-scale, well-designed study of 650 boys thought to be at high risk of developing delinquency was aimed at evaluating a prevention program. The outcome, as these individuals were followed over time, demonstrated that the treatment group fared less well than the control group for a range of delinquent behaviors. Such negative results, while disappointing, are important because they allow ineffective approaches to treatment to be abandoned.

These early controlled trials were the exception rather than the rule. Most studies of the effectiveness of psychological therapies consisted of treating a series of patients without a control group. Hence, it was impossible to be sure whether the results were due to spontaneous recovery or due to the treatment. Two developments catalyzed the use of the controlled trial. Hans Eysenck, Professor of Psychology at London University, reviewed the psychotherapy treatment literature in 1952 and again in 1966 (see Eysenck, 1952, 1966). On both occasions, Eysenck concluded that there was little evidence that psychotherapy was effective, that is, the results did not exceed the expected rate of spontaneous recovery.

 http://dx.doi.org/10.1016/B978-0-08-097086-8.21080-5

While this opinion resulted in a vigorous debate and defense of psychotherapy, including the addition of a few treatment trials that demonstrated some success for various forms of psychotherapy that Eysenck had not considered, Eysenck's conclusions were widely accepted, reaffirming the need for well-conducted controlled trials. Some, however, argued that the effects of psychological therapies, because they were aimed at 'inner' essentially unmeasurable changes, could never be adequately assessed in a controlled trial. This problem was largely overcome by the next development.

The second, and the most important, catalyst for the use of controlled trials of psychological treatments was the emergence of behavior therapy (*see* Behavior Analysis: Applied; Psychology, History of (Twentieth Century)). Eysenck (1966: p. 39) had concluded, "With the single exception of the psychotherapeutic methods based on learning theory, results of published research … suggest that the therapeutic effects of psychotherapy are small or non-existent …." Because behavior therapy was based on learning theory, the focus of treatment was directly on the problem behaviors comprising the clinical syndrome. This allowed for the development of objective measures of treatment outcome (*see* Behavioral Assessment for a complete discussion of objective evaluation methodology). In addition, because treatment was scientifically based, its practitioners were more likely to use scientific methods, including the randomized controlled trial, to assess the effectiveness of these new treatments.

Types of Controlled Trials

The most commonly used clinical trial design involves randomization of participants to two or more groups receiving different treatments. For randomization to be effective it is important that the treatment conditions are reasonably equivalent (*see* Placebo-Controlled Trials, Ethics of). For example, randomizing individuals to either a treatment or no treatment is not equivalent probably leading participants randomized to the no-treatment condition to drop out of the study more frequently than those in the active treatment, thus biasing the trial results. This situation can be addressed by delaying treatment for the no-treatment group. This design is referred to as a waiting-list control. However, this design only tests whether the new treatment is better than no treatment, a comparison that is of little scientific or practical use. Hence, a comparison with another form of treatment is preferable. Usually the number and duration of the treatment sessions will be the same in both groups controlling for many 'shared elements' among treatments and allowing differences in outcome to be assigned to operational differences between treatments. Controlled treatment trials should have a primary outcome to assess the differences between treatments, an outcome that measures as objectively as possible the primary behavior or symptom that the treatment is aimed at. For example, for panic disorder, the number and severity of panic attacks would comprise the main outcome; for depression, a measure of the severity of depression; for bulimia nervosa, measures of binge eating and purging. Because these measures test the primary hypothesis, that is, the null effect of the treatment in question as compared with a control group, the study should stand or fall depending on whether the primary outcome is positive or not. A clinical outcome is also often reported. For example, for panic disorder the number of participants in each group who no longer experience panic attacks would be such a measure. All controlled clinical trials, even or perhaps especially when outcomes are equivalent, should perform a moderator analysis that may throw light on subgroups of patients with better recovery in one or other of the treatments (see Section Predictors and Moderators of Outcomes). When the primary outcome is positive then secondary measures – usually associated psychopathology – are also examined for the effect of treatment. Because some symptoms such as mild anxiety or depression are normative in a community, the extent to which the treated population now approximates community norms may also be reported.

Complex Clinical Trial Designs

Because most treatments improve only a fraction of those with the disorder, a stepped-care design may be used to test the effects of adding a second treatment for those who do not respond to the primary treatment. There are three approaches to this design. First, the original treatment may be compared to an additive treatment (original treatment plus secondary treatment), thus allowing an assessment of the effects of adding a second treatment to the original treatment. Second, in what is known as an adaptive design (Nahum-Shani et al., 2012), the study may begin by treating everyone with the standard treatment and then randomizing treatment failures to either a second treatment or continuation with the standard treatment. This design requires a standardized measure of success or failure at the end of treatment and has the advantage of more closely following clinical decision making. The third option, again an adaptive design, depends on finding an indicator that predicts success or failure reasonably, accurately, and early in the treatment process. Many treatments are associated with a rapid response to treatment in a proportion of individuals often measured as a percentage decrease in the primary outcome early in treatment. For example, for bulimia nervosa, a 70% reduction of purging rates by week 6 of treatment has been shown to predict the treatment success or failure. Probable failures can then be randomly allocated to either the standard treatment or the new treatment. A variant of this design is to randomize participants into two groups and use the early marker in only one group to treat probable failures with a second treatment. Because only a fraction of patients fail treatment, these designs require a large sample size and may require a multisite study. However, such trials may lead to the development of treatment algorithms useful to clinicians.

Multisite Studies

Multisite studies provide more definitive estimates of effectiveness by increasing sample size and implementing the treatment in different sites that may have unique characteristics in terms of patient population, therapist characteristics, and so on. Hence, generalizability of the results of treatment to the clinical world is greater than in a single-site study. Another reason to conduct a multisite study is when treatment for

a relatively rare disorder is being studied. If the study were to be done at only one site it might take many years before sufficient participants were entered to the study. A multisite study provides more rapid results. Another reason for considering a multisite study is when the question of interest shifts to what treatment or treatments might benefit those who do not respond to an initial treatment as discussed earlier. Because only treatment failures will be entered into such a study, a large number of individuals must be treated in order to generate a sufficiently large sample for the study.

Multisite studies are necessarily more complex to carry out than a study at a single site. They are also more expensive than single-site studies and for that reason should be considered only when a reasonable number of single-site studies have suggested that a treatment is effective. The investigators involved in a multisite trial must agree to a common protocol. The treatment(s) being studied must be well documented in a treatment manual and therapists at each of the sites be trained in the delivery of the treatments. Moreover, the therapists should be carefully supervised throughout the treatment phase of the study to ensure that they are delivering the treatment(s) in accord with the protocol. A sample of tape recordings of treatment sessions should also be audited to ensure fidelity to the treatment. In addition, the assessments used must be standardized and performed comparably between sites. This may mean that assessors will also need to be trained and supervised across sites in the particular assessment methods. Because several sites are involved, data are usually collected by an independent data center responsible for collection and analysis of the data. The data center may also be responsible for the trial coordination.

Noninferiority Designs

Rather than hypothesizing that a novel treatment will be more effective than a standard treatment, an investigator may pose the question whether a novel treatment is similarly effective to a standard treatment. For example, there may be reason to think that a shorter, less expensive treatment may be similar in effectiveness compared to a longer, more expensive standard treatment or that a new medication will be similar to the standard effective medication. In this case, a noninferiority design may be called for. Sample size will vary according to the margin of difference that is set between the two treatments. If the new treatment's effect is within a small margin then it is very similar in effectiveness to the standard treatment. However, setting a small margin will necessitate a larger sample size. If the new treatment has not been tested against a placebo then a 3-group design including a placebo group may be required. With this design similarity to both the standard treatment and placebo can be determined.

Therapy Process

Although assessing outcome is the major aim of a controlled clinical trial, consideration of the processes underlying the outcome is also important to ensure that the results of the trial are valid (*see* Psychotherapy Process Research). Among the factors to be considered are following: factors common to all treatments such as the participant's expectancy of benefit, the therapeutic relationship, the fidelity of treatment delivery, therapist competence, and the adherence of participants to the key elements of treatment. Differences between treatments in any of these factors will threaten the conclusion that treatment differences are due to the specific elements that make up the treatment package.

Common Factors

Treatments can be regarded as a package containing both specific procedures aimed at a particular behavior or disorder, together with elements common to all therapies such as the amount of therapist attention, and therapeutic instructions that include the rationale for therapy together with engendering an expectancy that treatment is likely to be successful. Research has demonstrated that nonspecific elements lead to significant behavior change. Hence, it is important to know that to what extent procedures specific to the therapy contribute to a successful outcome over and above nonspecific elements. This raises a particular problem for psychological therapies because there is no placebo pill. This problem can be solved in several ways. The first solution is to use a nonspecific therapy, that is, one without the specific therapeutic procedures being examined and containing all the nonspecific procedures, but which also has face validity as a therapy with which to compare the active treatment. It is necessary to assess the participant's expectancy of a successful outcome to ensure equality between treatments, an assessment that should be made in all comparative treatment studies. Another design is to compare the new therapy with a standard therapy for the condition that has already been demonstrated more effective than a nonspecific therapy. This is the preferred design when a standard therapy exists.

Treatment Manuals

The treatment manual, a detailed account of the therapeutic procedures, was developed to facilitate the training of therapists and to allow others to replicate the treatment in further controlled trials and eventually in clinical practice. Such manuals are now regarded as an essential element of a controlled trial of psychological therapies. Therapists are trained to utilize the therapeutic procedures often in a didactic workshop in which the therapy is discussed in detail followed by therapists practicing the treatment on several patients before the controlled trial begins. During this period, therapists are supervised by an expert in the treatment and audio or videotapes of their sessions are audited and feedback is provided to the therapist. Often, a second, more advanced workshop is held when therapists have treated at least one patient. When therapists attain suitable fidelity to the treatment procedures, they are certified to begin treating participants within the clinical trial. Supervision of therapists continues throughout the treatment phase of the trial. There is some controversy regarding the use of treatment manuals. Some argue that manuals lock the therapist into a rigid method of providing treatment, thus eliminating the opportunity to individualize the treatment. Others suggest that manuals provide essential guidelines for therapists and that the experienced therapist can individualize treatment to the extent

necessary. There are relatively little experimental data on the effectiveness of the use of manuals in the clinic; however, existing data suggest that manuals are likely to enhance therapy probably by ensuring that the therapist stays on track during the treatment process. *See* Manual Based Treatments, for a complete discussion of this important issue.

Treatment Fidelity and Therapist Competence

Once the treatment phase of a clinical trial begins, therapy sessions are audio- or videotaped and a random sample of such tapes is audited using a checklist to ensure that all the elements of treatment are being provided, and that no foreign elements have crept in. Because the relation between fidelity and treatment outcome is at best weak, therapist competence that better relates to outcomes is often assessed. Hence, the auditor will determine if a specific element of therapy is present and also how competently that element was delivered.

Outcomes of Controlled Trials

There are several potential outcomes from a randomized clinical trial. First and foremost is whether the treatment is as effective as the comparison group; second, whether there are subgroups of patients who do best with the treatment under study; and third, whether variables that mediate the outcome of treatment can be identified. Such mediators may throw light on how a given therapy works.

Predictors and Moderators of Outcomes

It is usual in a controlled trial to assess whether baseline variables affect the outcome of treatment. Examples of potential predictors include the following: the duration and severity of the problem, the age and social class of the patient, and associated psychopathology. Unfortunately, such predictors are sufficient for a general description of the patient most likely to improve, but not specific enough to identify such patients before treatment begins. A more useful approach is to identify moderators of treatment outcome, an analysis that should be performed in all randomized clinical trials with two treatment groups. A moderator is a baseline variable that interacts with outcome, thus identifying groups of individuals with particular characteristics with better or worse outcomes. Because such individuals can usually be identified by a cut point on a questionnaire or a particular characteristic such as age, the identification of moderators is a clinically more useful predictor of outcome affording improved guidance to clinicians as to what therapy may work best for which patient.

Treatment Mediators

Mediators are either partially or fully responsible for an effective treatment outcome. They consist of a therapeutic procedure that occurs prior to the benefits of treatment and that significantly mediates outcome. Rather than measuring such variables before treatment begins, as is the case with moderators, potential mediators are measured early in the course of treatment usually on multiple occasions. Potential mediators are based on hypotheses about how the treatment works. The identification of mediators can throw important light on the mechanisms underlying the effectiveness of a given psychological treatment and may provide insight as to how to improve the treatment. See also Psychotherapy Process Research in which interactions between therapist and patient, and their effect on outcome, form the question of interest.

Cost-Effectiveness

The costs of treatment may inform which of two similarly effective treatments to use as a first-level treatment. There are two forms of cost: direct and indirect costs of the psychotherapy itself together with costs of ancillary treatments required during the treatment phase of the trial, e.g., hospitalization, medications, etc. These costs are usually fairly easy to acquire and are, therefore, most often reported. In addition, social costs such as employment of the patient and other family members, school attendance, home nursing, and visits to physicians or emergency rooms not related to the condition being studied may be monitored. These costs are more difficult to acquire because they need to be frequently monitored and may require a family member to report them in addition to the patient. Treatment costs are usually reported as cost per patient treated or cost per recovered patient.

Are Controlled Psychological Treatment Trials Useful?

There is still some controversy as to whether clinical trials for psychological treatments can reliably inform clinical work and social policy (Crits-Christoph et al., 2005; Weston et al., 2004, 2005). Criticism of evidence-based treatments includes arguments that such treatments have only been tested in settings that do not represent the 'real world.' To some extent this critique is true and more research needs to be performed in such settings. A further criticism is that clinical trials do not address the types of patients seen in community practice. This critique reveals a dilemma facing the clinical researcher. To reduce variability, narrowly selected clinical populations are usually entered into clinical trials. However, such selection methods exclude large numbers of treatment-seeking individuals. The converse approach would be to study treatments for a wide range of individuals with a particular disorder, hence excluding fewer individuals and better testing the limits of a treatment. Both approaches seem reasonable and the latter approach should be recognized as an important area for future research. Despite such controversy, the controlled trial has become the accepted method of evaluating the effectiveness of psychotherapy. Most individuals would prefer that their medical treatments were informed by controlled trials; similarly, consumers of psychotherapy should demand that these procedures are well tested.

Future Developments

The use of randomized controlled trials to evaluate the effectiveness of psychological treatments will undoubtedly

continue. A relatively large number of treatment procedures have been identified as effective for specific psychological problems (*see* Psychological Treatment, Effectiveness of and Psychological Treatments, Empirically Supported for a detailed review of such treatments). Many, but not all, such therapies fall under the rubric of behavior therapy. These research efforts have now generated a growing number of multisite trials in which the treatment is put to a more definitive test, compared with another effective psychotherapy, or with medication either separately or in combination with psychotherapy. As is the case in medical research, it would be expected that multisite trials will be increasingly used in psychotherapy research to obtain more definitive information concerning treatment effectiveness and beginning to answer the question: 'What psychotherapy is best for which person?'

In addition, clinical trials will be increasingly used to answer other questions important to psychotherapy research. For example, because moderator analyses are essentially exploratory in nature, the next step would be to test the effectiveness of using moderators as predictors of outcome in controlled trials to ascertain whether the information provided by a moderator enhances outcome. Another arena for controlled trials relevant to psychotherapy research is to compare different methods of training psychotherapists to accurately and effectively use particular psychotherapies. Such work will also lead to the development and testing of different methods to implement evidence-based psychotherapies in community settings. Different methods of delivering psychotherapeutic treatments are also being developed and such methods will need to be compared to standard treatments in randomized controlled trials. For example, treatments can be delivered to areas in which there are few therapists by means of videoconferencing. In addition, the Internet is now being used with increasing frequency to deliver interactive treatment packages. Internet trials where participants are not seen face-to-face pose a problem in terms of assessments that go beyond the use of questionnaires such as interviews. It could be argued that having in-person assessments would alter the participant pool. Potential participants who did not want to interact with anyone about their problem would be less likely to enroll in such studies, hence not representing the potential Internet pool of participants accurately. Nonetheless, optimal assessment methods must eventually be used to evaluate Internet-based treatments.

Finally, clinical trials will be used with increasing frequency to elucidate biologic mechanisms that are altered by psychotherapy and are associated with outcomes.

It may also be that the development of psychotherapies will ultimately be changed to better meet the needs of community therapists. At present, psychotherapies are designed and tested in somewhat rarified venues and community therapists are then expected to adopt them whether or not they meet the needs or practice of such therapists, particularly in clinics treating large numbers of patients. The development of adaptions of existing psychotherapies that better fit community practices should probably become a priority in the future development of psychotherapies. This will entail working more closely with therapists practicing in the community and developing and testing in controlled trials variants of psychotherapies adapted to particular settings (*see* Evidence-Based Psychotherapy).

Abstract

The history of psychologism is the history of an accusation and of a threat. To label authors as advocates of psychologism is to claim that they use psychological concepts and ideas in the wrong place. The accusation first became popular in the German-speaking world with the rise of experimental psychology in the second half of the nineteenth century. The most famous episode in the history of the accusation is the 'psychologism controversy' in the German-speaking world at the beginning of the twentieth century. Frege and Husserl were among the leading critics of psychologism in logic, mathematics, and epistemology. The German debate over psychologism influenced subsequent philosophical thinking in most Western countries.

The history of psychologism is the history of an accusation and of a threat. To label an author an advocate of psychologism is to claim that he or she uses psychological concepts and ideas in the wrong place. The accusation first became popular in the German-speaking world with the rise of experimental psychology in the second half of the nineteenth century. The most famous episode in the history of the accusation is the German 'psychologism controversy' at the beginning of the twentieth century. It will be the central topic of this article. It is widely accepted that this controversy played an important role in shaping the character of Western philosophy in general and analytic philosophy in particular. It also influenced subsequent debates over 'sociologism.'

The Psychologism Controversy in Early-Twentieth-Century Germany

From the 1880s onward, a number of German logicians and epistemologists started to attack some of their philosophical colleagues for presenting and endorsing the following kinds of 'psychologistic' arguments:

Logic studies specific 'laws of thought.' Psychology is the study of all kinds of laws of thought. Therefore, logic is a part of psychology.

Normative disciplines must be based upon descriptive-explanatory disciplines. Logic is a normative discipline with respect to human thinking. Psychology is the descriptive-explanatory discipline with respect to human thinking. Therefore, logic must be based upon psychology.

Logic is concerned with judgments, concepts, and inferences. Judgments, concepts, and inferences are human mental entities. Therefore, logic is a theory about human mental entities.

The touchstone of logical truth is self-evidence. Self-evidence is a human mental experience. Therefore, logic is about a human mental experience (and thus a part of psychology).

We cannot conceive of a radically different logic. The limits of conceivability are our mental limits. Therefore, logic is relative to the human species, and thus a subfield of human psychology.

In some cases, there was considerable dispute concerning the question who actually held these views. The first argument can be found in Theodor Lipps and Gerardus Heymans, the second in Wilhelm Wundt, the third in Wilhelm Jerusalem and Christoph Sigwart, the fourth in Theodor Elsenhans, and the fifth in Benno Erdmann. All the accused had published widely on psychological issues, and some of them openly advocated treating psychology as the foundation of philosophy.

Arguments against these and other allegedly psychologistic authors were provided by many writers, among them the logician and mathematician Gottlob Frege, the phenomenologist Edmund Husserl, and the Neo-Kantians Hermann Cohen, Paul Natorp, Heinrich Rickert, and Wilhelm Windelband. Of these and the many other critics, Husserl was undoubtedly the most successful. Husserl's arguments appeared in the Prolegomena to his *Logische Untersuchungen*. The following arguments figured centrally in the debate:

If logical rules were based upon psychological laws, then all logical rules would have to be as vague as the underlying psychological laws. But, not all logical rules are vague. Therefore, not all logical rules are based upon psychological laws.

If laws of logic were psychological laws, then they could not be known a priori. They would be more or less probable rather than certain, and justified only by reference to experience. But, laws of logic are known a priori; they are justified by apodictic self-evidence, and certain rather than probable. And therefore, laws of logic are not psychological.

If logical laws were psychological laws, they would refer to psychological entities. But, logical laws do not refer to psychological entities. And therefore, logical laws are not psychological laws.

All forms of psychologism imply relativism. Psychologistic thinkers take logic to be true only for the human species. But this contradicts the meaning of truth. Truths are unchanging and independent of the human mind.

A good deal of the psychologism controversy concerned the validity and originality of Husserl's arguments. Several commentators maintained that Husserl's first three arguments all begged the question. Others challenged Husserl's claim that the laws of logic did not imply matters of fact. Husserl's critics also denied that truths were eternal or independent of human thought.

The debate over psychologism was vigorous. This can be seen, for instance, from the fact that more than 130 philosophers were accused of advocating psychologism and that there were as many symptoms and definitions of psychologism as there were philosophical schools (Kusch, 1995). It was not merely the relationship between logic and psychology that was at issue, but the relationship between psychology and philosophy as a whole. This was a pressing issue not least because the practitioners of the then new (experimental) psychology worked in philosophy departments, and because between 1873 and 1913 the number of full professorships held by these 'psychologists' increased from 1 to 10. Of the 39 full professorships in philosophy in 1892, practitioners of experimental psychology held 3; of the 42 full professorships in 1900, they occupied 6; while of the 44 full professorships in 1913, they had already gained 10. Practitioners and advocates of the new psychology sometimes claimed that psychology provided the key to real progress in philosophy or that it was the heart of philosophy (Ash, 1995; Kusch, 1995, 1999).

This last-mentioned contention was opposed by a quickly growing group of 'pure' philosophers – led by the Neo-Kantians, and by Rudolf Eucken, Wilhelm Dilthey, and Husserl. They deemed it harmful to philosophy and its progress that experimental psychology should be regarded as part and parcel of philosophy. To put it another way, these philosophers believed that the role of the philosopher, as suggested by the academic success of experimental psychology, needed purification.

The prolonged debate between the advocates and opponents of psychology as a philosophical discipline was eventually brought to an end by World War I. The war brought about an atmosphere in which attacks on one's colleagues were regarded as utterly inappropriate. Moreover, it also led to a clear division of labor between pure philosophers and psychologists: While pure philosophy concentrated on the ideological task of celebrating the German 'genius of war,' experimental psychology focused on the training and testing of soldiers. After the war, both academic pure philosophy and experimental psychology had to cope with, and accommodate to, an intellectual environment that was hostile to science, rationality, and systematic knowledge. The project of a scientifically minded philosophy with experimental psychology as its central pillar quickly lost support. Advocates and practitioners of experimental psychology therefore had to find new ways of justifying their work. Many of them continued their wartime involvement with applied psychology (Kusch, 1995).

The Influence of the Psychologism Controversy

Psychologism and Sociologism

The way the psychologism controversy was fought by the defenders of philosophical purity became an important model for subsequent disputes between advocates and opponents of 'naturalism' (the view that philosophical questions can be answered using the results of the natural and social sciences). Many later arguments against 'sociologism' or 'biologism' closely mirror Frege's and Husserl's ideas.

For instance, in the German-speaking world the psychologism controversy of the first two decades of the twentieth century was followed by the dispute over the nature and philosophical aspirations of the sociology of knowledge. Accusations of 'sociologism' surfaced quickly and 'sociologism' was seen by many as the 'successor' to psychologism. Again many philosophers felt that a special science – this time sociology – was trying to occupy philosophical terrain. Critics of the sociology of knowledge accused it of both psychologism and sociologism, and in so doing, they drew on Husserl's work in particular. Defenders of the sociology of knowledge tried a similar feat in presenting their work as a bulwark against psychologism (Meja and Stehr, 1990). This idea has become a general feature of the field to this day (Bloor, 1983). The close link between the two 'isms' has been transmitted to subsequent Anglophone thinking mainly through the work of Karl Popper.

Psychologism and Philosophy

German-speaking philosophy at the beginning of the twentieth century exerted a powerful and lasting influence on philosophy in many other countries. Frege's (1893) and Husserl's (1970) antipsychologism thus became the dominant view in Western philosophy for much of the twentieth century. This is not to deny that other countries also had their own debates over the relation between psychology and philosophy. In the UK, for instance, George Frederick Stout and James Ward emphasized the philosophical significance of psychology; British idealists like Francis Herbert Bradley and Brand Blanshard were sympathetic to psychology, even though they denied its philosophical credentials; and realists like John Cook Wilson, Bertrand Russell, Herbert Joseph, and Herbert Prichard insisted on a separation. For Prichard, psychology was not even a 'proper science' (Passmore, 1994).

The institutional separation of psychology from philosophy eventually removed one important source of conflict. Once institutional separation had been achieved, 'pure' philosophers and 'impure' philosophers (i.e., psychologists) were no longer in direct competition over academic chairs. On the plane of ideas, however, the psychological challenge has remained. Throughout the twentieth century, psychology exerted a powerful pull on philosophers who wished to put philosophy on the sure path of a natural science. Willard Van Orman Quine explicitly called for a return to psychologism in the 1960s. Such calls have kept the psychologism accusation alive. Among the accused, one can find the names of Rudolf Carnap, Michael Dummett, Peter Geach, Nelson Goodman, Thomas Kuhn, John McDowell, Karl Popper, Wilfrid Sellars, and Ludwig Wittgenstein.

It is now common among historians of philosophy and psychology to lament the outcome of the psychologism controversy. The separation of philosophy from psychology delayed the development of research programs like 'cognitive science' that combine psychological experimentation with philosophical aspiration.

Psychology of Inferences

Janice M Keenan, University of Denver, Denver, CO, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The goal of comprehension is to understand what the speaker intended the text to mean. Inferences are driven by a desire to make the interpretation both more coherent and more elaborate than the text itself. The goal of research on inferencing is to specify how the computational processes involved in making inferences vary with the comprehender's knowledge, the conditions that promote inferencing, the various types of inferences and methodological problems involved in assessing them, and, most recently, the neural bases of inferencing.

From a legal perspective, inferences are easily defined by contrasting them with direct assertions. Assertions have physical representations, e.g., they exist on paper, whereas inferences do not; asserting a falsehood can lead to a criminal conviction, whereas implying a falsehood is typically not a crime. One of the important findings from research on the psychology of inferences has been the demonstration that this black-and-white distinction between inferences and assertions, which is so evident and straightforward at the level of the text, is not that consequential at the level of understanding the text. Because a comprehender's goal is to understand the author's message, not to represent the text, the information in the text is integrated with other information that the comprehender knows in order to construct an interpretation. What is important for constructing this interpretation is not where the information came from (the text or the comprehender's knowledge), but rather what it means and how it coheres. Inferencing is driven by a desire to make the interpretation both more coherent and more elaborate than the text. The goal of research on inferencing is to specify the conditions that promote inferencing, the various types of inferences that are made, the computational processes involved in making them, and, most recently, the neural bases of inferencing. Like any research domain, inference research has had its share of controversy and issues with methodological problems; nonetheless, the research has provided a solid foundation for understanding individual differences in inferencing. It is now clear that inferencing is not a single cognitive skill that individuals may be more or less good at. Inferencing is a set of processes that vary in their computational nature depending on both the comprehender's cognitive skills and the comprehender's specific knowledge relevant to the text.

Is Explicit Always Easier?

Although intuition might suggest that explicit information should always be easier to process than implicit information, one of the great insights of inference research has been to show that this notion of processing ease rests on a faulty assumption about the primary goal of language comprehension. It was initially thought that the goal was to construct a representation of the meaning of the text. In this view, explicit information is easy because it is direct, whereas implicit information requires an effortful process of determining what information is missing and then supplying it. Early studies of inferencing reinforced this view that inferring implicit information is more difficult than processing explicit information. For example, Haviland and Clark (1974) found it took longer to read a target sentence when the preceding sentence only implicitly mentioned the referent of the target sentence rather than explicitly mentioned it, as in:

Implicit: *Herb took the picnic supplies out of the car.*
Explicit: *Herb took the beer out of the car.*
Target: *The beer was warm.*

At the same time when reading time studies were reporting that implicit statements were more difficult to process than explicit ones, there were many early studies showing that, as far as memory was concerned, implicit information was functionally no different than explicit. For example, Bransford et al. (1972) found that people could not even recognize whether statements had been implicit or explicit when the statements could be integrated to form a story. Perhaps more remarkable was the finding that implicit information could be even more accessible in memory and easier to verify than information that was explicitly presented. Specifically, when statements refer to a linear ordering, e.g., *A is bigger than B*, *B is bigger than C*, explicit statements that refer to adjacent terms are more difficult to verify than implicit statements (e.g., *A is bigger than C*) referring to referents more distantly spaced in the ordering. These memory studies were soon supported by reading time studies, such as reported by Sanford and Garrod in their 1981 book, *Understanding Written Language*, showing that it took no more time to read *The clothes were made of pink wool* when it was preceded by the implicit *Mary dressed the baby* than by the explicit *Mary put the clothes on the baby*.

In order to accommodate findings such as these, the field underwent a change in its metaassumption about the goal of comprehension. The goal for the comprehender was no longer representing the text but rather representing what the speaker intended the text to be about. This was referred to as the mental model view of discourse. In this view, the difference between what is given and what must be filled in with an inference is defined relative to the comprehender's knowledge structures, not the text. But since knowledge structures cannot be observed and because they vary across individuals, the distinction is not

 http://dx.doi.org/10.1016/B978-0-08-097086-8.57011-1

as straightforward as when it is based on the text. The advantage, however, is that this perspective better explains the data. It allows explicit information to not always be easier than implicit. It also accommodates the fact that making information explicit is not even necessary for effective communication. For example, when two people know each other well, just a few words can function to activate the appropriate knowledge. It also accommodates the fact that being explicit can actually be objectionable. Try making all the thoughts behind even a simple sentence explicit. The result is typically the kind of incomprehensible verbiage found in legal documents; incomprehensible because the words serve to detour one from the intended knowledge structures.

The mental model view not only better accommodated the data, it also put the focus on specifying the computational processes involved in inferencing. How does the comprehender's knowledge get activated, and once activated, how does it get integrated with the text to build a model? Answering these questions involved first determining which types of inferences are drawn.

Types of Inferences

The question of which types of inferences are typically drawn during comprehension is important to answer not only for developing computational models of inferencing, but also for addressing the needs of other enterprises. One is the design of artificial intelligence language understanding systems; designers need to know which types of inferences people typically draw in comprehension so that they can program their systems to make the same inferences and thus function like typical natural language users. Another is the study of individual differences in language and cognition. The evaluations that are done in this field to determine whether someone has deficits in inferencing can only be done if one has a baseline understanding of which inferences are typically made by non-impaired individuals.

The most commonly drawn inferences are those that bridge a coherence gap between two textual elements, such as two phrases. Early research identified these inferences as *bridging inferences*; the example text given earlier involving *beer* and *picnic supplies* requires the comprehender to bridge the two sentences by inferring that the picnic supplies must have included beer. These are also called *backward inferences* because when a gap in coherence is detected, the comprehender works backward to build a bridge to the preceding text.

What constitutes a coherence gap is a function of linguistic features of the text as well as the comprehender's knowledge. The field is far from a complete theory of how a text maps onto that knowledge, but important steps have been taken in that direction. One is the identification of the dimensions of coherence. Several categories of cohesion signals and cohesive relations that exist in narrative and informational text have been specified and supported by research showing that inferences are made in order to maintain referential, causal, and temporal coherence. Furthermore, an automated system using these cohesion cues for assessing the coherence of texts, CohMetrix, has been developed (McNamara et al., 2010). Finally, the field has come to recognize how there exist individual differences in 'standards of coherence' – how much coherence the comprehender seeks (van den Broek et al., 1995). Those with high standards of coherence engage in more inferencing so as to achieve greater connectedness of the representation they construct, whereas those willing to tolerate less coherence will inference less. Individual differences in standards of coherence arise from factors such as motivation, relevant background knowledge, and purposes for reading. Standards of coherence vary not only across readers but also within the same reader across different reading situations.

Whereas backward inferences are made to establish coherence and are assumed to occur at coherence breaks in the text, *forward inferences*, also called *elaborative* or *predictive* inferences, merely elaborate the developing mental representation and can occur at any point. Compelling reasons have been proposed for why readers and listeners ought to make forward inferences, and it is often said that the more skilled the comprehender, the more forward inferences they make. But there are also costs associated with making such inferences. For example, if *spoon* is inferred from *stirred the soup*, reading a subsequent sentence about *the spoon* will certainly be easier if *spoon* is already in an activated state. However, if the text proceeds with some other construct, e.g., *stick*, mentioned as the instrument of the action, then the reader who inferred spoon will need to correct their understanding at a cost to their processing resources. The mix of potential costs and benefits associated with forward inferences has made them the focus of much research, primarily assessing the extent to which they are actually drawn. Research has focused on types of forward inferences thought to be most likely to occur: instrument inferences (e.g., inferring *spoon* from *stir the soup*), inferences about the likely consequences of events (e.g., inferring *cut* from *stepped on jagged glass*), and instantiations of general terms (e.g., inferring *cow* from *milk the animal*).

In a review of this research, McKoon and Ratcliff (1992) concluded that fewer of these forward inferences are drawn than what might be thought. They characterized the comprehender as operating according to what they called the *minimalist hypothesis*. It states that the only inferences that are reliably drawn are those required for local coherence and those involving activations of readily available preexisting associations. This started quite a controversy. To many researchers minimalism represented a return to the earlier text-centered view of comprehension. These researchers argued for a more knowledge-based, *constructivist* view (Graesser et al., 1994), and produced several studies arguing against minimalism by showing that even when texts are locally coherent, inferences related to global coherence are still typically drawn. Some of this controversy also revolved around methodological issues.

Methodological Issues

The main paradigms used to assess inferencing can be divided into two classes: *activation measures* and *memory measures*. Activation measures detect inferences by determining whether the inference concept is in an activated state relative to some control condition where the inference would not be expected to be drawn. Activation measures include reading times for a sentence where the inference might be drawn, reaction times

to make a lexical decision on the inference word or a word related to it, and time to name a word referring to the inference. Memory measures require subjects to access their mental representations of the text and determine if the inference is part of that representation. They include cued recall, sentence verification, question answering, and recognition tests.

Much has been learned about the methodological problems associated with each of the various measures (Keenan et al., 1990). The main problem with memory measures is that they do not allow one to determine whether the inference was made during comprehension or if it was made as a result of the test. Because memory tasks require a person to go back to their representation of the text to determine whether the information is present, they provide the person with another opportunity to draw the inference. This is a real problem if one seeks to know whether inferences are being drawn spontaneously at the time that the text is being understood or if they are only being drawn as the result of questions.

Activation measures have potential problems as well. First, not all activated concepts will get integrated in the comprehender's mental model as an inference. Some inference concepts may be activated spuriously by virtue of their association to other words in the text, a phenomenon referred to as word-based priming. For example, if the concept *dead* is activated by the sentence *the fashion model fell from the roof during the photo shoot*, it may either indicate that a forward inference was drawn about the model being dead from her fall or it may be that *dead* is activated because it is related to *shoot*. Thus, activation measures of inference require assessing activation relative to a sentence that controls for word-based priming. Second, the point in time when activation of an inference concept is assessed may affect whether or not it appears to have been drawn. Activation assessed immediately following the target text segment may suggest an inference was drawn; but if the inference is not incorporated into the long-term representation of the text, then a test occurring at the end of the passage may suggest that the inference was not drawn because the activation will have dissipated from not being integrated into the representation. Good methodology would suggest using multiple time points for assessment.

Because the different types of tasks used to assess inferencing can yield different results, it is important that research aimed at assessing whether inferences are made during comprehension use more than one measure of inferencing, with multiple control conditions, and assessments at various points in time. Converging operations such as these can help dispel the distorted picture of inferencing that can emerge when classes of inferences are confounded with the methods used to assess them.

Computational Processes in Inferencing

The computational processes of inferencing are not the same as computational models of these processes. The computational processes of inferencing are basically theories derived from experimental data of how text elements activate and generate knowledge structures during comprehension; these theories generate predictions that are tested in behavioral experiments. Computational models of inferencing, on the other hand, are particular instantiations of a theoretical framework on a computer. Examples are Kintsch's Construction–Integration model and van den Broek's Landscape model. Computational models provide an additional way in which to test theories because they provide simulation data that can be compared to data obtained from people comprehending the same texts; note, however, that when a model deviates from human behavior, it is sometimes difficult to know if it is because of its assumptions about inferencing or because of assumptions required to make the specific implementation run. Computational modeling has contributed significantly to unraveling the complexity of text comprehension processes by demonstrating for example how inference processes vary with dynamical changes to the reader's working memory, the specifics of retrieval mechanisms, and decision rules for integration.

It is clear from both empirical work and modeling that inferencing refers not to a single cognitive skill, but to a broad range of computational processes, varying from simply activating knowledge in the comprehender's memory to generating new knowledge structures. The outputs can similarly range in complexity, varying from a single concept (e.g., *spoon*) to a proposition (e.g., *that one event caused another*) to a set of propositions or schemas (e.g., *one's schema for romantic relationships*).

Kintsch's (1998) influential Construction–Integration model describes two computational phases of comprehension: first possible relevant knowledge structures are activated (Construction); second, there is an attempt to integrate these with the evolving representation of the text which has the consequence of selecting the interpretation (Integration). The computational processes of inferencing are similar. What varies across inferences is the complexity of activating information that allows the current text to be integrated and made coherent with the representation of what has been understood so far.

At the simplest computational level, inferencing involves merely activating concepts that a person already knows through a process called *automatic passive resonance*, where concepts that are associatively related to those explicitly occurring in the text get activated and integrated – e.g., activating *spoon* when comprehending *stirred the soup*. Concepts that get activated by passive resonance, however, may not always be sufficient to bridge coherence gaps. To illustrate with the earlier example about *picnic supplies*, *beer* is unlikely to get activated in most comprehender's minds by the phrase *picnic supplies*. In that case, when the comprehender encounters the phrase, *the beer*, a search of relevant information in memory is initiated to try to *retrieve* the fact that *beer can be a picnic supply*, and thus permit a bridging inference. This retrieval process requires more effort than producing inferences by passive resonance. If retrieval fails, then an even more computationally complex process of knowledge generation must take place. Using knowledge that the two sentences must somehow cohere and that definite reference is only used when a concept has previously been mentioned, the reader determines that *beer* must be considered part of *picnic supplies*. The reader thus makes an inference by generating this new knowledge.

It should be evident from this discussion that the ease of processing an inference is not just a function of information in the text. The types of computations required, and the cognitive effort required to construct an inference, can vary considerably

as a function of the comprehender's knowledge. The more knowledge one has, the less effortful inferencing is.

An interesting finding is the complex relation that exists between effort in drawing an inference and subsequent retention of the information. This is illustrated by studies of causal inferencing (Keenan et al., 1984), using two-sentence texts like the following in which various versions of the first sentence described a cause that varied in its relatedness to the event described by the second target sentence.

Highly Related: *Joey's big brother punched him again and again.*
More Moderately Related: *Racing down the hill, Joey fell off his bike.*
Less Moderately Related: *Joey's crazy mother became furiously angry with him.*
Unrelated: *Joey went to a neighbor's house to play.*
TARGET: *The next day his body was covered with bruises.*

Reading times increased as the relatedness of the sentences decreased, reflecting the likelihood that passive resonance from the first sentence produced the event described by the second sentence. However, as we noted above, when passive resonance fails, then more effortful memory retrieval or knowledge generation processes come to the fore. What is interesting is that these more effortful processes lead to better memory than passive resonance. When memory was tested for the causes by giving people the second sentence as a cue, moderately related causes were remembered best. The increased effort required to integrate moderately related causes improved retention, but only when the causes could be integrated. When they could not, as with unrelated sentence pairs, the increased effort did not aid memory. Thus, an inverted-U shape function was obtained between relatedness and memory.

Neural Bases of Inferencing

Early views of language and the brain proposed that higher-level language processes, such as inferencing, took place in the right hemisphere. This view was compatible with ideas about hemispheric differences derived from visual spatial research. Because left hemisphere processes were considered analytic, whereas the right hemisphere was integrative and synthetic, it fit that the integrative process of text inferencing would be right hemisphere. Two lines of evidence were also offered in support of this view. One came from behavioral studies of typical readers showing more activation of inference concepts when they were presented to the left visual field (right hemisphere) than to the right visual field. The other line of evidence came from patients with lesions to the right hemisphere; these patients showed great difficulty in drawing inferences to integrate sentences and maintain coherence.

More recent studies of the neural basis of inferencing in language comprehension using brain imaging (positron emission tomography (PET) and functional magnetic resonance imaging (fMRI)) have shown that while the right hemisphere makes a considerable contribution, it is not the exclusive domain of complex language processing. In a review of studies of the neural basis of inferencing during discourse processing Ferstl (2007) reported considerable evidence for left-lateralized or left-dominant activation. In addition, more recent behavioral studies of patients show that difficulties in inferencing are not just associated with right hemisphere lesions; they also occur when cognition is compromised for other reasons, such as developmental disabilities like Fragile X. Thus, inferencing does not appear to be confined to the right hemisphere.

The picture that emerges from imaging studies of the neural basis of inferencing is rather complex, as might be expected from the previous discussion of the varieties of computational processes that can underlie inferencing. Like the behavioral studies showing that there is not a single cognitive process underlying inferencing, imaging studies find that there is not a single underlying neural network involved in inferencing. The field has moved away from the idea of a one-to-one mapping of cortical activation on to specific cognitive processes – e.g., this area does inferencing – to thinking in terms of organizations of cortical regions into functional networks.

A variety of cortical networks appear to be involved in inferencing. The specifics of which regions participate in a particular inference depend on the difficulty of the inference being computed and the knowledge domain in which it is being made. Although imaging work on discourse processing and inferencing is still in its infancy, the networks tentatively identified as associated with component processes of inferencing according to Mason and Just (2011) include a coarse semantic processing network (right middle and right superior temporal areas), a network associated with the difficulty of the inference (bilateral dorsolateral prefrontal cortex), a network associated with memory for the inference (left inferior frontal and left anterior temporal), and different networks associated with different types of information being inferred, such as spatial inferences (intraparietal and middle occipital) and emotional inferences (right temporoparietal and medial frontal).

One of the first studies to show how the computational difficulty of the inference affects cortical activation was Mason and Just's (2004) imaging study of causal inferencing, using texts which varied in their causal relatedness like the Joey passage described above. They found bilateral cortical activation in dorsal lateral prefrontal cortex (DLPFC) that linearly increased as levels of causal relatedness decreased. This pattern was similar to what is typically observed for reading times on the second sentence; it reflects the differential effort required as the computational process of inferencing shifts from easily activating inference knowledge by passive resonance when the cause is highly related to more effortful processing when it is less related. Right hemisphere homologues of left hemisphere language areas appeared to be specifically involved in inference integration because they showed the same inverted-U previously reported for memory for the causes.

How the type of knowledge involved in the inference can also affect the specific cortical network activated was first demonstrated using PET imaging (Fletcher et al., 1995) of people comprehending passages on various topics. Differential cortical activation was observed when the topic required the comprehender to invoke a theory of mind to keep track of character's goals and feelings versus when it required understanding spatial configurations described in the text. This was an important finding because it showed

early on that there is not a single neural network associated with inferencing, and that the specific network activated depends on the passage content and the reader's knowledge. Imaging studies, which now use fMRI instead of PET, have recently replicated this finding of differential recruitment of cortical areas as a function of the type of knowledge required to make the inference (Mason and Just, 2011).

How the cortical networks associated with inferences differ depending on the type of knowledge involved is also apparent from imaging studies comparing individuals with and without autism. Cortical activation associated with reading passages that either required inferences based on intentions and emotional states or on spatial relations and physical causality was compared; deficits associated with autism were found for social inference networks but not those underlying other inferences (Happe, 1994). We can expect to learn more about the specifics of how inference processes map onto cortical networks as imaging researchers begin to do more research like this that focuses on individual differences and populations with cognitive and language deficits. Another avenue for future imaging research on inferences will likely involve understanding the brain activity associated with event segmentation and episode structure because inferences are often required to connect these segments. Together with enhanced imaging and enhanced data analytic techniques, studies manipulating passage content and the skills of the comprehender should shed light on the component processes of inferencing.

In sum, the neural basis of inferencing revealed through brain imaging studies supports the richly complex view of inferencing that has emerged from behavioral studies. Together these two sources should someday provide the basis for understanding why there are individual differences in inferencing skill.

Individual Differences in Inferencing

Studies of individual differences in inferencing often refer to it as a unitary skill; one that young readers need to develop, one that poor readers have a deficit in, and one that can be selectively impaired with brain damage. However, it should be evident from our discussion so far that such a view is an oversimplification. Inferencing is not a unitary skill with a defined locus in the brain. It represents a range of computational processes that vary not only with the skills of the comprehender but also with the comprehender's knowledge. Thus, individual differences in inferencing can stem from differences in knowledge as well as differences in cognitive skills. Young readers may therefore show less inference skill than mature readers in part because they have less knowledge of the world and its situations. Similarly, poor readers may appear to have deficiencies in inferencing that can be largely due to their having less knowledge (because they read less) as well as fewer resources to allocate to inferencing because of their struggles with word identification. Furthermore, knowledge differences are reflected in different neural networks, allowing inference deficits to be confined to a specific knowledge domain, as in high-functioning individuals with autism who show inference deficits only in the social–emotional domain.

Given the variety of skills underlying inferences and the fact that inference skill can vary even within an individual depending on the knowledge domain (Noordman and Vonk, 1992), the field is moving away from simply categorizing individuals as *generally* good at inferencing or generally poor at it. The focus of individual differences research now is to develop a deeper understanding of the cognitive and neural factors contributing to the range of differences across inferences of various computational types in various knowledge domains and to determine the extent to which these differences are due to variations in genes and environment.

It is important to note that the fundamental reliance of inferences on specific knowledge structures does not mean that knowledge differences are the only reason for individual differences in inferencing. Differences can also arise from individual differences in skills that inferencing processes draw on, such as working memory capacity, comprehension monitoring, or standards of coherence. For example, greater working memory capacity can facilitate inference processing because it permits more widely separated segments of text to be connected, and those who are better monitors and have higher standards of coherence will make more inferences in order to have a text be more coherent. Individual differences in component skills of inferencing tend to be positively correlated; so one goal of research on individual differences has been to determine whether performance on inference tests can be fully explained by individual differences in these component skills. If not, researchers make the case that separate inferencing specific skills are required to explain variance above and beyond that explained by component skills. A good example of such work is to be found in Oakhill and Cain's (2012) longitudinal study of children's comprehension processes.

It is common to think of differences in cognitive mechanisms as arising from biological differences coded by genes, and differences in knowledge arising mainly from the environments provided by family and schools. But recent studies using twins to assess the etiology of individual differences suggest a more complicated picture. Twin studies have compared the similarities of identical twins, who shared all their genes as well as family and school environments, to the similarities of fraternal twins, who shared their environments but only half their genes on average, in order to distinguish effects due to genes and to environment. Although there have been no twin studies of inferencing, it has been shown that individual differences in comprehension are largely explained by genetic influences, although environmental influences are also apparent (Keenan et al., 2006). At first glance, this may seem difficult to reconcile with what we know about comprehension and inferencing being so dependent on knowledge. Because knowledge is acquired from the environment, it might seem that influences on individual differences in comprehension might be more environmental than genetic. What the twin studies make evident, however, is that there are genetic influences on the cognitive and neural mechanisms that process that knowledge and determine the ease with which acquisition and use of knowledge occurs. These findings illustrate how important it is to examine genetics and understand their influence and interplay with

environmental variables like exposure to knowledge. We can expect that future research on comprehension and inferencing will represent a synthesis of cognitive, neural, and genetic approaches.

This article is a revision of the previous edition article by J.F. Masterson, volume 18, pp. 12405–12409, © 2001, Elsevier Ltd.

Abstract

This article explores the concept of selfhood from a variety of psychological perspectives. The psychoanalytic perspective offers a hypothesis that a stable core selfhood arises from a secure infant–mother relationship and grows in response to further interpersonal relationships in adult lives. The cognitive accounts offer additional models on how the self-concept is being maintained, clarified, evaluated, and developed with time and across different situations. The Buddhist perspective on selfhood nevertheless offers a radically different point of view about the value of selfhood in the maintenance of positive mental health.

Introduction

In the West, the self has all along been considered as an enduring entity, as established, for example, by Descartes, 'I think therefore I am' or by Freud, 'where Id was there ego shall be.' From the point of view of Western psychology, the self is unique in that it is both subject and object so that the self can be simultaneously experienced and observed. This duality of self allows people to think and talk about ourselves as both 'I' and 'me,' and thereby enables the two aspects of the self to converse with one another. Understanding how self and identity are constructed and maintained in healthy individuals enhances the understanding of the maintenance of negative self-views in psychological disorders. The experience of a continuous and coherent self is the result of complex interplay between knowledge, memory, experience, and various self-regulatory processes. Furthermore, the definition of self is also a dynamic interplay between self as an entity, the interface of self with others, and the interface of self with the outside world. The concept of self has been discussed and elaborated in different schools of psychology. The current article attempts to give an overview of the development of the concept of self, with due references to the psychoanalytic, cognitive behavioral, and existential schools of thought about development of self-concepts.

Self as an Entity: Psychoanalytic Perspectives

Influenced by his scientific education and by the ideas generally accepted in the cultural era that he worked, Freud first explained human motivation by reference to two innate instincts, the drives of sex and aggression. At the early stage of the evolution of his psychoanalytic theory of the self, Freud adhered to his academic background of basic science and proposed his first theory of anxiety as sexual instinct being damned up in the form of sexual tension that intruded into the consciousness (Freud, 1959). This idea tends to picture the psyche as a mechanism, an impersonal arrangement for securing detensioning, and a homeostatic organization. Acknowledging the shortfall of this theory, he revised this physical theory for a more sophisticated theory that anxiety was an ego defense reaction to danger that implied a signal in one's self-experience of some imminent threat. This is an important shift in Freud's theories that recognized the ego as the personal self. Freud further expanded this concept of selfhood by developing a more object-relation psychology (see below) of the influence people have on each other's lives, especially parents on children in the form of Oedipus complex. The shift of emphasis toward parent–child relationship led to the development of the superego, a mental structure that internalized the moral judgments, standards, and rules set by the parents and society at large. This led to the revision of the 'hydraulic' model to the 'structural' model of the self, viewing the ego as a control-system agency being tossed about among the instinctual drives, of the outside world, and of a forbidding conscience ('superego') (Freud, 1949). However, the incorporation of the superego into the above mentioned structural model can still be considered a mechanistic model, which explains behaviors as ego defenses against encroaching instinctual drives. Sullivan attempted to synthesize the mechanical model with the object-relations model by proposing that the biological substrates of personality as responsible for taking care of the appetites as organic needs, and the brain and the nervous system as the machinery of perception, thinking, and bodily functions. These substrates were then owned and operated within the psychic self or the ego (Sullivan, 1968). This model allows the overall state of the ego or personal self to determine the thoughts, emotions, and behaviors responsible for satisfying the organic needs. He also emphasized the importance of the subjectivity of experiencing as the true concern of psychodynamic studies. Sullivan also explored the growth of the individual ego in its ever-widening social milieu through interpersonal relationships. This marks a clear separation of interpersonal model of selfhood from a biological one as advocated by Freud.

On the other hand, Melanie Klein, Fairbairn, and Winnicott explored the internal psychic drama of the growing ego through tracing its development to its earliest beginnings in the context of infant–mother relationships. Klein regarded an infant as an arena for an internal struggle between life and death instincts. The immature ego of the infant is therefore exposed to the anxiety stirred up by the inborn polarity of instincts. The inner drama is projected onto the outer world, as

the infant's neurological systems develop the capacity to discern external objects. In other words, the infant only experiences the external world and objects through the lens of his innate makeup rather than through their actual behaviors to him. The death instinct is projected into the mother's breast to ward off his anxieties, which is then introjected, so that his experience of the outer world serves to increase and confirm his anxieties toward the internal dangers and inner conflicts (Segal, 1964). The external objects are therefore indispensable, as the infant needs them to project its death instinct onto them, beginning with the mother's breast. This first hate-object is necessary in order to project the death instinct that threatens the infant with psychic destruction. The first hate-object now becomes a real external threat as the infant has no means of dealing with it physically. In order to cope with this threat, the bad breast is now introjected as an object and not as an instinct. The external objects are therefore valued as receptacles for projection of instincts. The internal psychic life therefore consists of a hostile tension between two contradictory forces, and a pattern world is created into which the child's experience of the external world is fitted. What Melanie Klein did is to display the internal psychic life not as a battleground of instincts but a highly personal inner world of ego-object relationships. This inner world may come to conscious expression in play and dreams, and be disguised in symptoms and in disturbed behavior-relations to real people in daily encounters.

While Melanie Klein still developed her object-relation theories within the framework of life and death instincts, it is Fairbairn who considered the self as a unitary concept (Fairbairn, 1954). He argued that impulses could not be considered apart from object or ego-structures. The life of ego-structures is considered to be consisting of activities arising from impulses. He believed that there was a unitary dynamic ego that was primitive and undeveloped during infancy, which then further grew and developed with age. Mental health with preserved selfhood would then be regarded as a preservation of the ego wholeness in passing through the maturational stages on the way to adult maturity (Fairbairn, 1954). The entire process of growth, disturbance, and restoration of wholeness as an ego or personal self then depends on the ego's relations with objects, primarily in infancy, and thereafter on the object relations in real life. Whole ego development depends on good object relations in real life whereas split ego development occurs due to bad object relations in real life. This is where Fairbairn radically differs from Melanie Klein's views about split ego development arising from the constant battles between life and death instincts from the start. To Fairbairn, the infant is whole and will remain so if protected long enough by good object relationships in his encounters with the real world, starting from early relationships with his mother. Good object experience simply leads to good ego development. Extending the importance of good object relations in early life as suggested by Fairbairn, Winnicott proposed the concept of 'average expectable environment' as essential to the growth of healthy personality in the child, and the important element in it is the 'good enough mother' (Winnicott, 1965a). According to Winnicott, a continuously helping and facilitating environment that accepts the infant's immature dependence while supporting his tentative adventures into individuality and independence is essential for healthy personality development. With such a secure maternal environment, the child is then able to have a capacity to be alone (Winnicott, 1965b). The infant does not feel he has lost his mother when he cannot see her and he does not feel isolated when he is physically alone. This built-in experience is considered by Winnicott to last for a lifetime as a foundation on which all the child's later growth can take place. Winnicott believed that, when an adult develops this mature capacity to be alone without feeling isolated, he will then be able to enjoy solitude, delve into creative work, and commit himself to his true values and life goals (Winnicott, 1965b). The above psychoanalytic accounts of the development of self-concept suggest that the current theories have moved from the Freudian concept of control of instincts to the development of a stable core of selfhood through a good mother–infant relationship at the start of life.

Self as an Entity: A Cognitive Perspective

While psychoanalytic writers have provided different models in explaining the development and splitting of selfhood, the writers from cognitive science provided different models in explaining similar phenomena. Markus (1977) introduced the concept of self-schemas, which are cognitive structures that help to organize, summarize, and explain behavior in a particular sphere of life. Self-schemas serve as templates that represent connected beliefs about the self. These schemas help in the processing of information about the self through selective attention to certain information consistent with the current self-schemas and filtering out of information that are inconsistent or threatening to the self-schemas. As the current self-view depends on the combination of self-representations at any one time, it is better considered as a working self-concept (Markus and Nurius, 1986). If viewed from the framework of self-schemas, one can consider that a particular working concept is active when a particular set of self-schemas are being activated (Beck et al., 1979). If the self-concept can take on different working self-concepts at different times, it is possible that the self-concept can take on the form of 'possible selves' (Markus and Nurius, 1986). These possible selves are cognitive structures that represent concepts about what a person may become, what he or she would like to become, and what he or she is afraid of becoming. People with positive selves tend to experience more positive affect and persist longer on tasks than those with negative selves (Fluery et al., 2002). At times, possible selves may be represented by their own images being involved in certain situations or performing certain tasks. These images may have powerful effects on emotions being experienced and on increasing the likelihood to act in response to these images (Ng et al., 2013).

Possible selves may also be viewed from another perspective. Higgins (1987) suggests that people have an 'actual' self or self-concept, an 'ought' self with beliefs about obligations and personal standards, and an 'ideal' self with beliefs about personal aspirations. Studies have found that discrepancies between different selves may trigger different feelings (Strauman and Higgins, 1987). People with depression are more likely to experience actual–ideal discrepancies while those with anxiety are more likely to experience ought–ideal discrepancies. It is conceivable that these are self-concepts in

imagination. Yet studies have found that these concepts may be crystallized in the form of future-oriented (prospective) images about oneself. For example, patients with depression were found to have negative prospective images (Morina et al., 2011) while those with hypomania had positive prospective images (Gregory et al., 2010). Another related concept is self-concept clarity, the stability of self-concepts in terms of clarity of content, consistency across different situations and at different times. People with low self-concept clarity are highly susceptible to external environmental influence, so that their feelings of self-worth will be highly dependent on the outcome of social events. Indeed, studies have found that people with low self-concept clarity are more likely to be anxious, depressed, and have low self-esteem (Butzer and Kuiper, 2006). Conversely, people with frequent emotional swings are also more likely to have low self-concept clarity, as the individual may experience very different working self-concepts when excited, depressed, or anxious compared to normal mood states.

The above discussion mainly focuses on the content of the self-concept. However, the manner in which self-concepts are being organized may also have a profound impact on mood states. Showers (1992) proposed two types of self-organization: compartmentalized and integrative. In compartmentalized self-organization, positive self-beliefs and roles are segregated clearly from negative ones in the form of separate knowledge structures. There is no overlap between the attributes that are used to describe these two different aspects of the self. For example, a person with compartmentalized self-organization may describe himself or herself as being incompetent and weak as an employee but as being supportive and caring as a friend. However, a person with integrative self-organization will describe himself or herself with both positive and negative attributes. When asked about their performance as an employee, he or she might still coin negative terms like 'incompetent' or 'lazy' but also add positive terms like 'reliable' or 'loyal.' In other words, their views about themselves in different roles are more likely to be less extreme or dichotomous, with positive information being available to balance against negative information. Indeed, people with compartmentalized self-organization were found to be more likely to experience extreme mood swing in response to social stress than people with integrative self-organization (Showers, 1992). As self-images are likely to contain a collection of absolutely positive or negative attributes about oneself, people with compartmentalized self-organization may be more likely to report having intrusive self-images (Luke and Stopa, 2009). Indeed, negative self-images have been reported by people with a wide range of psychological disorders (Hackmann and Holmes, 2004). It is worth noting that this concept of self-organization has close similarities with Fairbairn's concept of split ego formations as a result of poor mothering.

Buddhist Concept of 'No Self'

As shown in the last section on psychoanalytic perspective of self as an entity, psychoanalysts strongly believe the importance of a strong ego as a key to success in interpersonal relationships and pursuit of life goals. A stable and clear self-concept is also considered in the cognitive science field as conducive to positive mental health. As knowledge arises in the context of cultural influence, it is understandable that a heavy emphasis on a stable core of selfhood as being conducive to adult maturity may be a product of Western culture (Williams, 1997). For many Buddhists, the existence of a conventional self-concept is only accepted on a relative level of reality. The self is affirmed as a nonenduring entity arising from countless mental and physical aggregates. This false self-representation is considered as being constructed through avoidance of non-pleasurable feelings and as being nourished by pleasant sensations. Such attachment to incessant cravings is considered as the cause of sufferings in life. The self is perceived as a false belief, an illusion leading to the creation of a sense of false continuity that resists the impermanence that comes with life (see the section on stability of self over time for a Western view). If the self is a construct that leads to suffering, this faulty perception is to be deconstructed and replaced with the notion of 'no self' (Michalon, 2001). Through this cultivation of a nonenduring self, an individual will perceive the interconnectedness of himself with the rest of the world and the reason for his existential suffering (Engler, 1986). The means of achieving this awareness of 'no self' is through meditation that leads to deconstruction and reorganization of one's inner ego world (Engler, 1986). This perspective is in direct contrast with the psychoanalytic and cognitive accounts that emphasize on the importance of establishing a stable, clear, and positive self-concept.

Stability of Self Over Time

The above discussion on self-concept clarity has highlighted the importance of temporal stability of self-concepts in the maintenance of personal well-being. Yet even people with high self-concept clarity will have a shift of self-concepts with time, usually in the form of a sense of growth and development of the self over time (Sedikides and Gregg, 2008). To have a sense of continuity of self across time, one will need to have an ability to access past memories. According to Conway and Pleydell-Pearce (2000), autobiographical memories are events that are recalled from the past and are stored in a self-memory system. Such a self-memory system contains these autobiographical memories and current self-relevant goals, and regulates the environmental cues required to access this knowledge base. People are motivated to enhance the self by recalling the past and predicting the future in a manner that make themselves more favorable (Ross and Wilson, 2000). People usually recall their past selves as more negative or mixed than their current self, and they view their future selves as more positive (Ross and Buehler, 2004), thereby contributing to a sense of growth and development.

A breakdown in this system is likely to lead to a failure to link the past with the present self-concepts. For example, a traumatic event may lead to an experience of vulnerability and precede the onset of post-traumatic stress disorder. The memories of the traumatic events may be used as evidence for the existence of the new self-concept as being a weak and vulnerable person. Failure to retrieve past autobiographical memories that contradict this new self-concept would add to a further sense that the old self has died (Stopa, 2009).

Furthermore, lack of access to such autobiographical memories would also reduce the ability to solve current stressors based on past learning experiences, thereby leading to the maintenance of the psychological disorder (Williams et al., 2007) and the new emerging negative self-concept. In addition, generic memories without specific details may provide general evidence that supports global and dysfunctional self-views, whereas specific, episodic memories with great details about the circumstances may help to contextualize a negative outcome as caused by a set of specific circumstances. Such autobiographical memories will then serve as convincing evidence that the negative outcome is not caused by certain global, internal, and stable self-attributes that are less amenable to changes.

While the above cognitive accounts focus on how the past information would affect the current self-concepts, one can readily discern that both psychoanalytic and cognitive science writers both placed a heavy emphasis on the importance of past experiences in shaping current self-concepts. On a different note, existential writers provide an alternative account on how future information might affect current self-concepts. A threat to the meanings in one's life in accordance with one's culture worldview can lead to various cultural worldview defenses, including harming those people that threaten these meanings and rewarding those who support these meanings, so as to protect one's self-worth. When death is becoming apparent or imminent to a person, a person will approach individuals who offer protection and comfort their life meanings and avoid those who threaten these meanings (Arndt et al., 2002). Reminding individuals with obsessive-compulsive disorder about the salience of death and enhancing their awareness of their death anxieties can exacerbate the frequency and intensity of compulsive rituals (Strachan et al., 2007). Furthermore, people with high self-concepts were found to have lower death anxiety and fewer cultural worldview defenses than people with low self-concepts (Strachan et al., 2007).

Self-Regulation and Self-Monitoring

The individual has both a self that can be observed, monitored, and evaluated (the object) and a self that does the judging (the subject). Self-regulation and self-evaluation are important processes that facilitate people to reflect upon and to monitor who they are, what they aspire to become, and what they would like to avoid becoming. There are a number of contrasting motives for self-evaluation. The first one is self-enhancement motive, which describes the wish to elicit positive information and to discard negative information about the self. The second one is the self-verification motive, which describes the search for consistency within the self. The third is the self-assessment motive, which describes the search for accurate information about the self. The fourth is the self-improvement motive, which describes the search for information that will lead to self-improvement. People tend to search for positive, consistent, accurate, and improving information from other sources (Taylor and Brown, 1988). However, when faced with different types of information, people tend to search for information that enhances their self-esteem (Sedikides, 1993). Once the motive of self-enhancement has been met, people are then more likely to be receptive to negative feedback that may help one to improve in the future (i.e., fulfilling the self-improvement motive) (Trope and Pomerantz, 1998). What is intriguing is that people with psychological disorders tend to put the self-verification motive before the self-enhancement motive when seeking out personal information. Therefore, they are more likely to seek information consistent with their negative self-views and filter out information that disconfirms their negative self-views (Giesler and Swann, 1999). The relevance of other motives of self-regulation to psychological disorders is not systematically studied so far.

Self-Affirmation and Self-Compassion

Self-affirmation is about increasing the positivity of the self, especially after a threat to self-esteem, while self-compassion is about accepting the self as it is. Affirming an important value is the most common method of self-affirmation, which is activated when the self-concept is under threat (Steele, 1988). This is consistent with the self-enhancement motive to seek out positive information to maintain high self-esteem. Such self-affirmation strategies have been found to be helpful in reducing depressive ruminations and increasing positive mood (Koole et al., 1999). On the other hand, self-compassion is concerned about accepting oneself for one's faults and failures and viewing such experiences as normal human experiences necessary for growth and maturation. It is considered as having three components: self-kindness, mindfulness, and common humanity (Neff, 2003). Rather than focusing on positive aspects of the self, self-compassion focuses on kind and compassionate acceptance of self as a human being with flaws and limitations. People with self-compassion are less likely to be self-critical, anxious, or depressed, and are more likely to be associated with greater life satisfaction (Neff et al., 2007).

Self-Awareness

Another aspect of the self being the subject of observation of the object of self is the concept of self-awareness. It refers to the concept that one is aware of the independence of self from others and of having independent thoughts, feelings, and behaviors from others in this world. Objective self-awareness is defined as the tendency to focus on the self and compare the self against a standard (Duval and Wicklund, 1972). The standard is a representation of what constitutes the right attitude or behavior. This concept is similar to the actual-ought selves discrepancy (Higgins, 1987) and, to a certain extent, the structural model of anxiety as proposed by Freud (Freud, 1957), except that there is an emphasis on triggering a restorative mechanism of consistency through changing attitudes, behaviors, or standards. If the inconsistency cannot be resolved, there is a vicious cycle of increasing focusing on internal states, decreasing attention from external cues for problem solving or seeking disconfirmatory evidence, and increases avoidant behaviors (Wells and Mathews, 1994). In support of the dysfunctional nature of excessive self-focus, heightened self-awareness has been found in people with depression (Schwartz, 2001) and anxiety disorders (Bogels and Mansell, 2004). People with negative self-evaluations

(and negative self-beliefs) would have exacerbations in negative affect when they increased their self-awareness (Figurski, 1992), as enhanced self-awareness would lead to increased attention toward body states, negative emotions, and avoidant behaviors. The role of heightened self-awareness in maintenance of psychological disorders possibly explains why mindfulness and self-compassion (in which self-compassion includes mindfulness and commonality of humanity) are beneficial to mental health.

The Self through Interaction with Others

The self does not develop in isolation. People define themselves through interactions with other people at different stages of life. During childhood, the self is defined through interactions with family members, classmates, and teachers at school. In the above section on 'self as an entity,' the psychoanalytic writers of object-relations school are the scholars who wrote extensively about the importance of early object relations in the development of personality and selfhood. John Bowlby, another child analyst, suggests that early attachment experiences (e.g., parental care) influence the development of internal working models, which are important variables in subsequent social behavior throughout the life span (Bowlby, 1980). These internal working models are complex emotional-cognitive schemas that contain feelings of self-worth and beliefs about the availability and responsiveness of important attachment figures, which guide subsequent behaviors. If a child has received consistent and sensitive care from parents, they are likely to develop a positive internal working model of high self-worth and of perceiving significant others as reliable and trustworthy. However, if a child has received inconsistent care, neglect or even abuse, he or she will view himself or herself as unworthy and significant others as unreliable or trustworthy (i.e., a negative internal working model). Hazan and Shaver (1987) has hypothesized that internal working models have direct impact on subsequent adult romantic relationships. Bartholomew and Horowitz (1991) have delineated four different attachment styles: secure, preoccupied, fearful, and dismissive. The latter three styles were also considered as insecure styles. People with a preoccupied attachment style have a view of unworthy self but a positive view of others. People with a fearful attachment style have a view of unworthy self and a negative view of others. Finally, people with a dismissive attachment style have a positive view of worthy self but a negative view of others. An insecure attachment style has been associated with anxiety disorder, bipolar disorder, various personality disorders, and schizophrenia (Dozier et al., 2009). The internal working model is in fact quite similar to the self-schemas with associated emotions, beliefs, attitudes, and behaviors as mentioned in the previous section.

Apart from this interpersonal model of interactions of self with others, a more direct model of social interaction with others in the formation of self-concept is provided by social comparison theory (Festinger, 1954). Festinger believed that people would compare themselves with others when there was inadequate information to understand about their own personal abilities. Depending on the intimacy of the targets of social comparison and the importance of tasks in question, different affects could be elicited through social comparisons. For example, people feel worse about themselves when they are outperformed by someone close to them on a task or an attribute that is considered as important to them (Beach and Tesser, 2000). Individuals with low self-esteem tend to engage in social comparisons when comparisons are unfavorable, thereby maintaining their negative self-concepts about themselves (Santor and Yazbek, 2006). People with depression are more likely to compare with people who outperform themselves (i.e., upward comparison) (Butzer and Kuiper, 2006). Furthermore, the domains of performance selected for social comparison depend on the personality of the individuals and the perceived importance of the domains in attracting the interest of others (Thwaites and Dagnan, 2004). For example, dysphoric individuals with autonomous personality are likely to compare their achievements with others (Wood and Lockwood, 1999). In addition, people with anxiety disorders tend to make upward rather than downward social comparisons (Antony et al., 2005).

Conclusions

The psychology of self is unique in that the self can act as both the subject and the object. The self as a subject can observe, monitor, and evaluate the self as an object. Both the content of self-concepts and the processes of organization are key areas that require further research and understanding. Current understanding of psychological disorders appears to focus on the contents of cognitions and cognitive processes leading to negative affect and maladaptive behaviors. Yet the current models of the entity of self and the interactions of self with others provide testable hypotheses for understanding of the contribution of these models to the onset and maintenance of psychological disorders.

Abstract

From the Pre-Socratic Greeks to Wundt's day, the history of psychology has followed shifts in epistemology. Are the senses to be trusted? Is rational analysis more reliable than experience? Such questions have shaped the conduct of science, and relate to psychology in that way, but are also intrinsically psychological. This article traces the evolution of epistemology from Ancient Greece and Rome into Medieval Europe, then the Renaissance, and on to Descartes. From there, both Empiricism and Rationalism are detailed, and their connection to the advent of academic psychology is discussed.

The history of psychology is at least as old as the history of humankind. Nicholas Humphrey (1983) notes that earliest humans not only sought to understand, predict, and control nature, but also each other. Indeed, the survival of early humans was tied to their ability to observe and then anticipate what their comrades were feeling and intending: What in modern parlance we call Theory of Mind. This though, is by definition, prehistorical. History begins when we have enough artifacts to extract a theory or practice. Psychology then, like most other academic disciplines, typically starts its history with the Pre-Socratic Greeks.

Pre-Socratic Philosophy

The relevance of the Pre-Socratic Greeks, indeed of much that will be covered herein is found in the evolution of epistemology. Are the senses to be trusted? Is rational analysis more reliable than experience? Such questions will ultimately shape the conduct of science, and relate to psychology in that way. These questions also invited speculation about perception and reasoning itself, and as such are intrinsically psychological.

Thales (*c*.625–547 BC) has been called the 'first philosopher,' though he would have pointed to mathematicians and physicians in Egypt and Babylon as providing him a foundation. For Thales (and us today), the world was made up of a finite number of elements. This begged the question of which element might be the most primary or fundamental. Using both natural observation and reason, Thales concluded it was water – as all life depends on water. Although Thales is rightly heralded for giving a data-based and rational, as opposed to a mystical account, it was not long before his literal analysis of the matter came to be challenged.

Heraclitus (*c*.540–480 BC) argued that it was neither water, nor air as others had asserted, but fire that was the most fundamental element. Unlike Thales, who had pointed objectively to the water in things, Heraclitus reasoned that all things change, and that fire as the essence of change itself, was thus the most primary of the elements. Since all things change, even those that exhibited no observable fire still shared in its essential nature. This foreshadows much that will follow in epistemology, as it calls into question the value of empirical observation (from our limited senses) as opposed to rational analysis.

Pythagoras (*c*.580–500 BC), like Heraclitus, favored reason and trusted its revelations about reality over what the senses observed. Pythagoras held that the *logos* (as in logical structure) for everything in the cosmos was found in mathematics, and in numerical *ratios* (the root of the Pythagorean's rationality). Practical demonstrations using geometry and music showed that true relationships could be determined through mathematical analysis far more accurately than from empirical observation. Although it is a bold statement, it can be argued that real roots of modern scientific psychology began here with Pythagoras. To the degree that we have confidence (at least at $p < .01$) in what our statistical findings and models can tell us about the general principles of human nature, we are following a tradition that begins with Pythagoras and moves forward across the span of Western civilization. That is, scientists trust the results of their statistics and mathematical models even when they extend beyond the limits of our direct sensory capabilities.

The Golden Age of Greece

Pythagorean ideas were adopted by the later Greeks. The entrance to Plato's Academy stated "Let no one without an understanding of mathematics enter here," and by that he was endorsing the Pythagorean approach. Alcmaeon, usually seen as the first to offer a 'scientifically' grounded approach to medicine, was also a Pythagorean. And building upon the tradition of Alcmaeon was the greatest of Greek physicians – Hippocrates (*c*.460–377 BC). Indeed, Hippocrates was such a great figure that for more than thousand years works written by others would be credited to him so they would be accepted as authoritative. This leads historians to speak more often about Hippocratic writings than the writings of Hippocrates.

Hippocratic writings held that human nature was controlled by chemicals, and that health (both mental and physical) was a matter of keeping these chemicals in proper ratio. The modern treatment of depression and anxiety by medications that increase or block various neurotransmitters is the exact same idea. Even aspects of the ethical code endorsed by contemporary clinical psychologists can first be seen in the Hippocratic oath: "I will not abuse my position to indulge in sexual contacts with the bodies of women or of men… Whatever I see or hear,

professionally or privately, which ought not to be divulged, I will keep secret and tell no one."

Socrates (*c*.470–399 BC) is seen as a major transitional figure in the history of Western philosophy. During Socrates' day Athenians reveled in 'philosophical disputation' of every kind – from human nature to natural science to politics – these Greeks loved an academic argument. In turn, this love of debate afforded an entire class of what is perhaps best understood as private tutors called the Sophists.

In addition to speculative philosophy (most often a form of Skepticism – or the belief that objective truth is often unknowable), the Sophists taught logic, politic, and rhetoric to those early advocates of democracy, serving very much the role of a modern political (or advertising) campaign manager. Indeed, it was their willingness to sell their knowledge and expertise, at times to the highest bidder in a political debate (instead of backing the side that was 'right') that, although consistent with their Skepticism, has earned them derision.

Socrates differed from most of the other Athenian Sophists in that he sought to find the universals or essences that formed the basis of our concepts: What do all beautiful objects have in common? Even such a fuzzy and subjective concept as beauty could be defined then using inductive reasoning. Once so defined, philosophers could also communicate with one another objectively about the concept, which challenged one of the central assumptions of Skepticism.

Like the Sophists, Socrates understood that knowledge meant power. But, Socrates advocated self-exploration as a variant of the day's popular skeptical philosophy. He taught that the very purpose of life was to gain knowledge and from that, personal wisdom. Socrates most famous student, and erstwhile chronicler, was Plato (*c*.427–347 BC).

Like the Pythagoreans, Plato understood that although mathematical relationships were abstractions that could not be experienced through the senses, they were nevertheless real and provided the 'schema' (logical form) for everything in the empirical world. This, in a nutshell, is his Theory of Forms. The thousands of birds that one encounters with the bodily senses are but empirical instances of an ideal bird form that exists in the abstract. For Socrates, essences were merely defining features, but Plato's forms had an actual existence separate from their manifold worldly occurrences.

In his Allegory of the Cave, Plato describes prisoners who have lived their entire lives in the depths of a cave as a metaphor to show the relationship between our knowledge and the forms. Above and behind the prisoners is an unseen path, and as the masters pass by with various objects shadows are cast onto the wall in view of the prisoners. These shadows are all the prisoners know of the world, and constitute the reality given by their senses. Imagine now that one of the prisoners was to escape, and see then the path, people, and objects for what they 'really' were instead of mere shadowy reflections.

Holding the allegory in abeyance, exactly how does one come to know the forms if not through sensory experience? The answer must be that such knowledge is innate, and as such Plato was a nativist as well as a protorationalist. Plato's ideas as sketched here were revitalized in the heyday of cognitive psychology through Eleanor Rosch's work on conceptual categories and Noam Chomsky's idea of an inborn deep grammatical structure. Indeed, when more than 2000 years later, Alfred North Whitehead quipped that the history of Western philosophy is but "a series of footnotes to Plato" he was affirming that Plato had advanced the ideas of the Pythagoreans that would come to shape Western civilization's continued fascination with scientific understanding.

Aristotle's (*c*.384–322 BC) father was the physician of the Macedonian king, and in time Aristotle himself would tutor the Macedonian prince that would grow up to be Alexander the Great. Aristotle studied for many years with Plato in Athens, but also traveled extensively. Around age 50, Aristotle returned to Athens and soon took over one of its famed schools, The Lyceum. With a large staff, library, museums, and 'laboratories' it certainly resembled a modern university. Perhaps more accurately, it could be said that when 'modern' universities were being developed in Europe, they followed an Aristotelian model.

The most amazing thing about Aristotle is the scope of his work. His writings on logic, metaphysics, epistemology, ontology, ethics, and aesthetics are still taught at face value, and in some cases continue to represent philosophy's best understanding of these matters. His thoughts on language, rhetoric, and poetics essentially shape how Western civilization composes its written works (from dramatic narrative to technical argument). Given his substantial and enduring contributions to natural science, he is rightfully viewed as the patriarch of such diverse modern studies as optics, physics, biology, botany, taxonomy, and geology (among others). Arguably, his impact on medicine, theology, and political science has been greater still. And yet, perhaps the contemporary field that he most clearly anticipated was psychology. Aristotle wrote about the physiology of our sense organs, sensation and perception, consciousness, sleep and dreams, learning, memory, language, reasoning, executive functioning, emotion and motivation, development, morality, pedagogy, pathology, and social behavior. Indeed, as one flips through the chapters of an introductory textbook there is little therein that Aristotle did not address.

Of all these topics, his postulation of laws of association is clearly the most important. It was Aristotle who first understood that recall occurred in accord with principles of contiguity (when we think of a thing, we also think of things that were experienced with it) and similarity (when we think of a thing, we also think of things that are like it). Indirectly then, Aristotle explains learning as a function of the frequency of these associations. From the British Empiricists (below) to the first academic psychologists (e.g., Alexander Bain, William James, Wilhelm Wundt), on to American Behaviorism and even modern day neural networks, these insights would explain learning and memory evermore.

It is tempting to describe Plato as the 'grandfather' of rationalism, and Aristotle as the 'grandfather' of empiricism. Aristotle did believe in empirical information as a source of data, but also that such sensory information was to be used as the basis for rational analysis. As Immanuel Kant might have understood him, for Aristotle sensory experience was necessary, but not sufficient, for generating knowledge. For Aristotle (like Thales long before him) knowledge came from the application of reason to empirical data.

Considerations of Ancient Greece typically conclude with a look at the sorts of 'folk psychology,' or everyday philosophical

beliefs that were widely endorsed. Many different –ism's existed, but Epicureanism (from Epicurus, *c*.341–270 BC) can serve as example. This was a materialistic theory emergent from the Greek's understanding that everything in the cosmos was composed of atomic particles. As such, there was no immaterial soul that existed after death. Since there was no afterlife, the goal was to make the most of this one, and that led to a clever version of hedonism.

Epicurus wrote "I am thrilled with pleasure in the body when I live on bread and water, and I spit on luxurious pleasures, not for their own sake, but because of the inconveniences that follow them." Hedonism is the pursuit of pleasure, but the Epicurean insight was that absence of pain was the greatest of pleasures. Stated more bluntly, *overall* there is more pleasure to be had from avoiding the hangover, the bloating, and genital itching than there is from such 'pleasures' as drunkenness, gluttony, and risky sex – followed then by the hangover, indigestion, and all that scratching.

Rome

Popular culture tends to treat all parts of the Ancient World the same. In truth, the sociology (or a day in the life) of Golden Age Greece could not have been more different from Rome after Caesar. The Greeks flourished in the anarchy of democracy, but the Romans prized law and order. Whereas the Greeks valued speculative philosophy, the Romans found it useless. Rome was so fiercely pragmatic that by the height of the Empire even Plato would have been all but unknown. What the Roman's valued they excelled at – their roads, aqueducts, sewers, and architecture are truly marvelous even when set against modern engineering efforts. The battle plans and field medicine that drove the Legions are still in use today, after some 1500 years of warfare.

Roman education and philosophy was no less practical. The goal was productive citizens, efficient cogs in the machine that was Rome. The best example of this comes from Marcus Aurelius' *Meditations* (written just before AD 180). This masterwork of Stoic philosophy came to define a good Roman citizen. Good Romans were expected to accept their lot in life and be dutiful without question: "To live each day as though one's last, never flustered, never apathetic, never attitudinizing – here is the perfection of character." Pleasure came in realizing that one had done their best, and was part of a grander plan, even if that plan was unknown or inconvenient to the individual. Pain comes from reaching beyond one's station, from worrying about things beyond one's control.

In 312, just before the Battle of the Milvian Bridge, the emperor Constantine is said to have had a vision that changed history: the Christian cross in the sky, accompanied by the message "By this sign you shall conquer." Christianity soon became a tolerated, then favored, and within 75 years, the official religion in Rome. From Rome to Europe, from Europe to the World, Christian ideals have certainly influenced how Western civilization thinks about virtually everything, including psychology.

To the extent that there is an actual Christian psychology, it is to be found initially in the New Testament writings of Paul (*c*.10–64, and himself a Roman citizen). Soon however, church figures such as Augustine (*c*.354–430) would become the most significant thinkers for the next 1000 years.

The Middle Age

There is no one date that historians agree to be the start of the Middle Age. From the sack of Rome by the Visigoths in 410 up through events in the early 500s, several dates are offered. Historian generally do agree that the Middle Age was the confluence of three things: (1) the vast infrastructure of roads and cities built by the Roman Empire; (2) the ideas and ideals of Christianity; and (3) the largely Germanic peoples that now controlled what would become Europe. Indeed, the Middle Age is roughly the next 1000 years, during which Europe is formed.

The beginning of this medieval period is also referred to as the Dark Ages, as following the fall of Rome the 'light of knowledge' grew dim in what would become Europe. Matters begin to improve, albeit slowly, following the creation of Charlemagne's Palatine School in the late 700s. Nevertheless, education remained limited to priests, monks, and the nobility for generations. Indeed, the Middle Ages are often skipped over within academic histories, viewed as an anti-intellectual time utterly dominated by the Church. This is an unfortunate oversimplification, as surely the legacy of Roman pragmatism contributed as much to the absence of speculative thought as did the Church itself.

Just after AD 1000, a new era in which philosophical reason and theological faith are united begins. The name most associated with the start of this movement is Anselm (*c*.1033–1109), who felt that secular logic could be used to support religious beliefs. Such ideas are generally known as *scholasticism*, and one of the important early scholastics was Peter Abelard (*c*.1079–1142). Within philosophy Abelard is best associated with the 'realism versus nominalism' debate, a consideration akin to that which we introduced with Socrates and Plato concerning the nature and universality of the essences that define our concepts. Concurrent with scholasticism was the development of schools and even major universities (Abelard lectured at the cathedral school in Paris); and also, the Crusades.

Whereas Greek thought had barely survived Rome and the Dark Ages, its preservation and study had continued with far less disruption in the Middle East – lands now under sway of Islam. Via the Crusades, works by Aristotle and a variety of other Greeks made their way into those fledgling European universities. Additionally, there came new innovations in science and mathematics penned by Islamic scholars, as well as detailed analyses of Aristotle's vast psychology by thinkers such as Al-Kindi, Avicenna, and Averroes.

Scholasticism would come to be associated with the renewed study of Aristotle, and following the model of Islamic scholars, the integration of Aristotle's philosophy (and psychology) with theology. Such was the life's work of Albert Magnus (*c*.1200–1280), and his student Thomas Aquinas (*c*.1225–1274), the most heralded of the scholastics.

The latter part of the Middle Age is filled with colorful figures who would anticipate much of interest to modern psychology. From William of Occam (*c*.1285–1349) we get his razor, or admonition that explanations should always be kept as simple as possible and devoid of extraneous

assumptions. This 'law of parsimony' is now seen as a cornerstone of science, and was a guiding principle of early animal researchers such as Conwy Lloyd Morgan and the ethologists. And as a final example, Ramon Llull (*c*.1232–1315) sought to mechanize Aristotelian logic. As such, he is surely the father of computational approaches to generating knowledge, and perhaps even of computer science (see Bonner, 2007).

The Renaissance

Renaissance means 'rebirth,' and was a time (from the mid-1400s to the early 1600s) when philosophical thought in Europe gradually switched from being God-oriented to being human-oriented. It was concurrently a rebirth of objective inquiry and a rejection of authority. It was fueled by many convergent factors – such as the explorations of Asia and the New World, the advent of movable type printing in the West (it had long been known in China), the continued 'rediscovery' of Western civilization's past (Greece and Rome), and the rise of a new movement commonly known as 'humanism.'

Humanism is characterized by its focus on the individual as opposed to an establishment (such as the Church, the Guild, the State, even Aristotle). Key figures in the intellectual history of the Renaissance include Leonardo da Vinci (1452–1519), Niccolo Machiavelli (1469–1527), Desiderius Erasmus (1466–1536), Martin Luther (1483–1546), Juan Luis Vives (1492–1540), and William Shakespeare (1564–1616), all of whom would have an impact (direct or indirect) on psychology.

In addition to philosophy, the Renaissance afforded a resurgence in science. It was the age of Nicolaus Copernicus (1473–1543), Galileo Galilei (1564–1642), Johannes Kepler (1571–1630), and Isaac Newton (1642–1727). Although a general foundation for scientific inquiry was provided by these giants, the figure most aligned with psychology was Francis Bacon (1561–1626). A witty and clever critic of Aristotle, he shared the man's belief that nature could best be understood by studying it directly. Whereas Galileo (in the Pythagorean tradition) advocated the discovery of general principles that could be formulated mathematically and from which deductions about nature could be made, for Bacon science should be based only on the facts of observation. Bacon feared that theory-laden observations would be biased, and this led to his very psychological consideration of our idols – or those aspects of our nature and experience that color our perceptions and cognitions.

The idols of the cave refer to how our knowledge influences our perceptions. When a child and a divinity student are told a simple Biblical parable, do they really hear the same thing? The idols of the tribe are those biases inherent in human nature, what the modern philosopher Ludwig Wittgenstein would call our 'form of life,' and why, as he claimed, "If a lion could speak, we could not understand him." The idols of the marketplace are the confounds to reasoning introduced by communication itself. Elizabeth Loftus and John Palmer (1974) famously reported that subjects estimated the speed at which two cars struck very differently if prompted by "how fast were they going when they smashed" versus "how fast were they going when they bumped." And, the idols of the theater concern the influence of our allegiances. Albert Hastorf and Hadley Cantril (1954) had students from Princeton and Dartmouth watch clips from a football game between those teams, then answer questions about controversial plays. Results correlated with which school the subjects attended.

Bacon believed in a 'better life through science' and may have been the first to write that "knowledge is power." His approach is seen as an important forerunner to positivism (considered below), and was consciously accepted by B.F. Skinner (1956) and his behavioral followers.

Descartes

Rene Descartes (1596–1650) is typically seen as the transitional figure between the Renaissance and what is called the 'Modern' era in intellectual history. Modern does not exactly mean contemporary, but more that the era's questions and their answers are still seen as relevant to our time.

Famed as a mathematician (e.g., the Cartesian coordinate system) and as a psychological philosopher (e.g., *Cogito ergo sum*), Descartes was also a military engineer and amateur biologist. Although much in his philosophy is still considered both valuable and 'modern,' for psychology there has perhaps never been a more important question than the mind–body problem.

The story often begins with Descartes' interest in the mechanical automatons at St. Germain. In the gardens there, the statues of animals and mythological creatures were animated as onlookers unknowingly triggered elaborate hydraulic and pneumatic systems by their own movements. The amazing result was sounds and actions that seemed both lifelike and situationally appropriate.

Understanding that the automatons shared much with human anatomy – an articulate skeleton, a sort of musculature, and an extensive network of tubings to convey liquids, Descartes pondered what the difference really was? Were we not just biological machines of the same sort? And like the automata, might not our behaviors just be programmed reflexive responses resulting from environmental stimulation?

Descartes came to believe that all animal behavior (and most of our own behavior and cognitive activity) could be explained mechanically. He was compelled however to view at least part of the mind (and his Catholic soul) as immaterial, and as such not part of the physical body. That then is *dualism*, or the belief that the mind and body are separate entities. But given that, what is the relationship between this incorporeal mind and the material form? That alone would get us a mind–body problem, but for Descartes it was worse still, as he also imagined that the immaterial mind could causally influence the corporeal body. How then could that happen? How could a thing without substance act on the physical world?

Descartes offers some thoughts on resolving the problem (including that the pineal gland might somehow afford this metaphysical interaction), but not a satisfactory resolution. He is famous then for giving us the problem, and what a fine problem it is, as no universally accepted to solution (that still supports dualism) has yet been discovered.

In 1649, Descartes assumed a position as tutor and court philosopher to Queen Christina of Sweden. Within 6 months

he fell ill and died. Sixteen years later it was decided that his remains should be returned to France. Somewhat ironically (given his mind–body problem), the coffin was too short, so the skull was removed to be shipped separately. Although the body was interred in Paris, the head was stolen and spent over 150 years in various private collections before reaching the Academie des Sciences (Boakes, 1984).

Empiricism

Although it is anachronistic to say that the epistemological debate between Empiricism and Rationalism goes back to the Greeks, a tension between the place of knowledge gained by experience and knowledge given innately or gained by reason certainly does. One side of the debate would come to be best expressed by a series of philosophers known as the British Empiricists, the British Associationists, as well as related French thinkers. This tradition will eventually lead to Bain, (aspects of) Wundt, and Edward B. Titchener, as well as American Behaviorism.

Bacon (above) has been suggested as the first British Empiricist, and Thomas Hobbes (1588–1679) analysis of human nature is also often considered a good starting point for empirical 'psychology' given his interest in such topics as instinct, appetites, attention, and thought. Nevertheless, it is John Locke (1632–1704) who provides us with the most complete view of this position.

Locke was a physician by training, but likely thought of himself as a political scientist. For Locke, to understand the optimal political system meant to understand man, most especially the origins of what he claimed to know. Locke strongly disagreed with Descartes that certain ideas were innate, arguing that if true, then all men should reason the same. For Locke, the alternative was that we were born 'as white paper' and that experience writes on us. For Locke, ideas came to us passively, from sensation. As such, our minds automatically take in (as ideas) the sensations that experience provides. Locke also believed that the mind actively reflected on those ideas, which explained reasoning, memory, etc. That is, although Locke did not believe in any innate ideas (only those acquired passively from sensation), he did accept intrinsic and active mental faculties.

Simple ideas from sensation could through the reflective processes become more complex ideas. Likewise, Locke believed that ideas could be associated with the experience of pleasure and pain, and thus emotions such as fear could be explained (sensing fire is associated with pain, hence I come to be afraid of fire). Locke (following Aristotle) also understood that some ideas are naturally associated based on contiguity and similarity, and was even aware that ideas could come to be spuriously associated. In fact, he clearly anticipates several points from modern behaviorism, including conditioned aversions and superstitious learning, even outlining a 'behavioral therapy' for removing such.

George Berkeley (1685–1753) and David Hume (1711–76) are usually portrayed as extending Locke's work on sensation and association, as well as bolstering it philosophically. Berkeley's most psychological contribution came in showing how complex perceptions arise from basic sensations. Hume starts with the same assumption as Locke – that understanding human mind is a prerequisite for the study of politics (and science itself), but sought to enrich Locke's system by adding a consideration of causality and expanding on the role of association.

Hume wrote "There is no relation which produces a stronger connexion in the fancy, and makes one idea more readily recall another, than the relation of cause and effect betwixt their objects." It was certainly not Hume's aim to deny that cause and effect exist in nature, but it was his goal to question how we *know* these relationships. We see one billiard ball roll across the felt and strike another, which now begins to move. In fact, we may have seen this many times. Naturally we infer cause from what we have seen and that we have seen it repeatedly. But upon reflection, we surely did not *see* a cause (transfer of force), merely a conjunction of events. It is only by belief and custom that we accept what we have seen as causal.

The major British associationists typically include David Hartley (1705–57) as well as James (1773–1836) and his son, John Stuart, Mill (1806–73). The associationists (as the name suggests) sought to further analyze the associative processes of the mind – culminating in what can be called a 'mental chemistry,' and advancing empirical philosophy ever nearer to the advent of an autonomous academic psychology.

In 1749, Hartley published *Observations on Man, His Frame, His Duty, and His Expectations* which was a combination of physiology and theological philosophy. Although today we would consider almost all of it factually false, it is nevertheless a milestone in the history of psychology. Specifically, Hartley's juxtaposition of the questions of philosophy with the methods of physiology would mark an important step toward psychology having its own niche among the academic disciplines. That niche would be to bridge the philosophical questions about mind and moral behavior with the data of physiology. In Great Britain, this goal soon comes to be realized with the work of Alexander Bain (1818–1903).

French philosophy of the era was often an extension of Locke, or a response in some way to Descartes. Etienne Bonnet de Condillac (1714–80) provided an enduring (and wonderful) example of empirical thought through his 'sentient statue,' whereas Francois-Pierre Maine de Biran's (1766–1824), like the associationists, sought to further understand associative learning. Pierre Jean Georges Cabinas (1757–1808) was a physician during the French Revolution whose interest in the mind–body problem even led him to study those executed by the guillotine. And, Julien Offray de La Mettrie (1709–51) believed that Descartes knew the truth – that man is a machine – but had been unwilling to speak it. Rejecting Dualism for Materialism (there is only matter) La Mettrie had no such fear, and gleefully articulated the view that mind *is* brain – a position that is still endorsed by most psychologists today. La Mettrie also saw a continuity between animal and man, and provides a logic that would serve subsequent scientists who believed that the study of animals could advance (even human) psychology.

Also associated with the wider aims of empiricism is Auguste Comte's (1798–1857) positivism (as in, to posit, or assert as foundational). What was being posited as foundational was an understanding based on science over religion. Even in the 1800s the Church was still taken as the authority

on many matters, and it was Comte's goal to see that authority displaced by science (the rational analysis of empirical data). Subsequent positivists, such as Ernst Mach (1838–1916), would in turn be instrumental in establishing guidelines for the proper conduct of valid science. In fact, science and positivism came to be so widely acclaimed in the industrial revolution of the mid-1800s that Romanticism emerged as a response. Fearing that a place for human emotional experience was being lost, and building on such thinkers as Johann Wolfgang von Goethe (1749–1832), intellectual attention shifted to understanding phenomenological experience. Although psychology was to become a science, it continues to feature some aspects of phenomenology, and echoes of the tension between positivism and Romanticism remain.

Rationalism

Where the empiricist emphasizes sensory information and postulates a relatively passive mind that functions according to mechanistic laws, the rationalist postulates an active mind with preexisting content (innate structures and/or concepts) that interprets data from the senses. The earliest rationalists include Baruch Spinoza (1632–77) and Gottfried Wilhelm von Leibniz (1646–1716), both of whom were influential and eclectic thinkers. For example, Leibniz (independent of Newton) developed calculus, devised early computing machines, and his unique monadology. Importantly for our story, he also disagreed with Locke, and Leibniz' alternative views would form the basis of German Rationalism.

Immanuel Kant (1724–1804) was a disciple of Leibniz, but it is said that reading Hume's analysis of causation awakened him from his 'dogmatic slumbers.' Kant would argue that a priori (innate) knowledge of matters such as space and time must exist for us to make sense of our experience. Even Hume's analysis of causation as perceived correlation relied on an innate understanding of time, specifically the notion of before and after. Kant did not postulate specific ideas as innate, but 'categories' that were used in organizing sensory experience.

Kant would also seek to redress the ethical view of Utilitarianism that had emerged as a part of the empirical tradition (e.g., Jeremy Bentham, 1748–1832). This was a sort of hedonic calculus in which the good or pleasurable was weighed against the bad or painful – the right action being the one that produced the greatest good. In contrast, Kant proposed a categorical imperative, according to which, "I should never act except in such a way that I can also will that my maxim should become a universal law."

Like Plato before him, Georg Wilhelm Friedrich Hegel (1770–1831) believed the goal of philosophy was to understand the nature of the cosmos, what Hegel called the Absolute. Our sensory experience of some small part of it was of little value; what was needed was to find the underlying rational structure of reality. For Hegel, this structure was the dialectical process in which a thesis interacts with its antithesis, and the result produces a synthesis, which is also a new thesis, and so the dialectic continues. In ways both overt and subtle, Hegel's thought can be seen in almost every academic discipline in the late 1800s, psychology included.

Existentialism, as typified by Soren Kierkegaard (1813–55) and Friedrich Nietzsche (1844–1900), emerged in part as a response to Hegel's idealism. With its focus on subjective experience as opposed to rational analysis, existentialism would come to have a profound influence on psychology, especially early 'clinical' psychology. To summarize existentialism with a short cliché: "Never let other people do your thinking for you." That is, to explain our psychology mechanistically or nativistically is to give away the importance of the individual, and the free choices of will.

Beyond Kant and Hegel there were other rationalists with a direct connection to psychology, such as Arthur Schopenhauer (1788–1860), and the Scottish School founded by Thomas Reid (1710–96). Adherents of the Scottish School advocated a consideration of the mind as a collection of faculties united by a common sense, or executive function. This school was especially popular as a moral philosophy, as a model of mind endorsed by the physiologists of the day, and in America's first universities.

Just as empiricism culminates with Bain's psychology in Britain, rationalism will produce a German psychology. Johann Friedrich Herbart's (1776–1841) works include his *Textbook in Psychology* (1816) and *Psychology as a Science Based on Experience, Metaphysics, and Mathematics* (1824–25). The *Textbook* was certainly not the first work on psychology per se, but may be the oldest volume wherein psychology is being treated as an actual (independent) academic discipline. Similarly, Rudolph Hermann Lotze (1817–81), like Hartley before him, would advocate for an independent academic psychology that would juxtapose physiology (and medicine) with philosophy. Lotze would live to see Wundt, 1879, and all that, and his own Chair at Göttingen would next be filled by the famed early *psychologist*, G.E. Müller.

Abstract

Twentieth-century academic psychology emerged formally in 1879, originally defined as the science of mental life, with the goal of uncovering the facts of consciousness. Evolutionary theory expanded its emphasis on how mental processes and behavior function to help organisms adapt to environments. The study of learning dominated the early half of the twentieth century, with the goal of predicting and influencing behavior. Various subfields and a positivist emphasis on experimental methods led to consolidation of the discipline by midcentury. Technological developments stimulated resurgence of the study of cognition and neuropsychology and increased disciplinary fragmentation later in the century.

Nineteenth-Century Foundations

Modern academic psychology emerged during the latter part of the nineteenth century as a way of addressing age-old questions regarding human nature and built upon work in biology, physiology, medicine, and philosophy – particularly philosophical debates over explanations for how humans develop knowledge, how humans represent environmental objects in conscious awareness, and how best to account for human behavior (Hergenhahn and Henley, 2014; also see article on the Psychology, History of (Early Period)). Twentieth-century psychology built upon these and other topics and branched out into a wide variety of issues, theories, and methodologies. This article addresses psychology as an academic undertaking, primarily in the form of an experiment science, thus (unfortunately) omitting discussion of the many applied areas of psychology that are covered in the encyclopedia article on the history of clinical psychology, including the important influences of psychoanalytic theory, other theories of personality and psychotherapy, and psychological testing and measurement, which also had a large impact on the work of academic psychologists.

Hermann von Helmholtz's (1821–94) mechanistic approach to physiology and his contributions to understanding the physiology of visual and auditory perception, along with such findings as Paul Broca's (1824–80) and Carl Wernicke's (1848–1905) identification of localized brain functions, stimulated research into the relationship among sensations, brain processes, and conscious experience, and in particular, the measurement of these relations. Ernst Weber (1795–1878) pioneered the study of psychophysics – the relationship between physical characteristics of objects and the psychological perception of them. He asked people to discriminate the weight differences of two objects by comparing a target weight with a standard and determined the relationship between the physical weight of the object and the participant's perception of whether the object was heavier than, lighter than, or equal to the standard. From these data, he derived the just noticeable difference (jnd) – the smallest weight that the participant could discriminate – and found that the jnd did not reflect an absolute weight difference, but rather a ratio that is relative to the weight of the standard. This finding, in 1834, Weber's law, is regarded as the first 'law' in psychology.

Further research by Gustav Fechner (1801–87) confirmed and refined Weber's law, generalized it to auditory and visual stimuli, and, in 1860, stated it mathematically that sensations increase arithmetically as physical stimuli increase geometrically (Weber's law), indicating that humans perceive sensations relative to the background context in which they occur. Building on Fechner's work, Hermann Ebbinghaus (1850–1909) studied the processes of learning and memory as they occurred and his findings, still regarded as valid today, demonstrated that forgetting occurs rapidly during the first few hours following learning and then declines more slowly. He also found that learning distributed over a period of time led to better retention than massed repetition at a single time and that overlearning already memorized material reduced the rate of forgetting.

Charles Darwin's (1809–82) theory of evolution stimulated an interest in individual differences among people in terms of intelligence and personal characteristics, based on the assumption that such differences might account for success in adaptation and survival. Darwin's English cousin Francis Galton (1822–1911) began attempts to measure intelligence, following the British empiricist tradition, by emphasizing innate sensory acuity as the primary way humans come to know and adapt to the world. His work led to statistical concepts such as the mean and correlation, which became central to the twentieth-century psychology emphasis on quantitative analysis and the search for general principles. Charles Spearman (1863–1945), also in England, studied the relation between sensory acuity and children's success in school and suggested that an overall inherited factor, called general intelligence, accounted for most of intelligence, with specific factors reflecting learning and experience. In France, Alfred Binet (1857–1911) pursued the measurement of intelligence from the Continental rationalist perspective by measuring a variety of complex mental operations that reflected his view of intelligence as active and complex, rather than a single ability, and that could be nurtured rather than being fixed by inheritance. While a revised version of Binet's intelligence test became the most popular method for assessing children's intelligence in the USA, most psychologists adopted Spearman's general factor understanding of intelligence.

Beginnings of Experimental Psychology

Voluntarism, Structuralism, and Phenomenology

Scholars typically date Wilhelm Wundt's (1832–1920) founding of a laboratory for psychological research at the University of Leipzig in 1879 as the formal beginning of modern psychology. Wundt's voluntarism, which focused on the active processes involved in selective attention, incorporated the work of Helmholtz, Weber, and Fechner into an organized research program that employed scientifically controlled introspection to determine the underlying processes involved in human conscious awareness of environmental objects. He viewed the goal of psychology as identifying general principles of perception and learning that applied to all normal, adult humans by identifying how higher-order concepts derived from raw sensory elements. Wundt built on the European Continental rationalist tradition's view of a structured, active mind that transforms sensations and particularly focused his research on selective perception, the question of what determines how, among the entire perceptual field, people attended to specific sensations and objects.

Following his graduation from Oxford, Edward Titchener (1867–1927) studied with Wundt but followed his native British empiricist tradition, which emphasized a blank mind that passively builds up perceptions through association of sensations. He came to the USA in 1892 and developed a successful doctoral program in psychology at Cornell University. His structuralist approach pursued the search for mental elements further by attempting to identify the immediate experience of raw sensations and determine the laws through which they combine to make perceptions and more complex mental phenomena, attempting to create a chart of psychological elements analogous to chemistry's period chart of elements. Although Titchener trained many doctoral graduates who became highly productive and well-known psychologists, his structuralist approach declined, primarily because even highly trained introspectionists could not agree on how to describe a raw sensation, and the retrospective nature of their descriptions hampered the attempt to study sensory events as they occurred.

European phenomenologists, such as Franz Brentano (1838–1917) and Carl Stumpf (1848–1936), opposed the emphasis on raw sensory elements and championed a phenomenological approach that attempted to understand consciousness in terms of whole, meaningful, intact perceptions, mental processes rather than contents, and the functional nature of mental acts. Edmund Husserl (1859–1938) further proposed that scientific psychology should examine the pure phenomenology of personal subjective experience, and he searched for mental essences and meaning. These phenomenological approaches influenced Gestalt psychology and existential approaches to psychology during the twentieth century.

Functionalism

The publication of William James' (1842–1910) Principles of Psychology in 1890 incorporated and elaborated on each of these traditions and expanded the field to embrace any useful topic or methodology that would shed light on the human condition. Influenced by Darwin's theory of evolution, James' functionalist psychology emphasized how mental processes serve to aid adaptation to the environment and included the study of individual differences as well as general principles, the application of psychology to improving the human situation, and the study of behavior as well as consciousness. James likened consciousness to an unbroken stream rather than a chain of independent elements, emphasizing its personal, continuous, and impermanent qualities and its function in enhancing adaptation to the environment. His views on habits, the self, emotion, volition, and cognition, along with the importance of useful practical applied psychology, elaborated by other functionalist colleagues such as John Dewey (1859–1952), James Angell (1869–1949), and Harvey Carr (1873–1954) established a foundation for the eclecticism of twentieth-century psychology. The functionalists also embraced a pragmatist philosophical perspective that rejected the positivist search for independent truths and instead proposed that the validity of ideas and theories lay in their usefulness in solving human-defined problems and anticipating future events.

Behaviorism

The desire for a more objective approach to psychology, which would avoid the subjectivity of studying conscious experience and using introspection, led Russian physiologists Ivan Sechenov (1829–1905), Vladimir Bekhterev (1857–1927), and Ivan Pavlov (1849–1936) to propose that psychology studies the relationship between environmental stimuli and behavior, both physiological and overt responses. The American psychologist John Watson (1878–1958) adopted Pavlov's respondent conditioning approach and elaborated on this view with his Behaviorist Manifesto, in 1913, which proposed that the goal of psychology should be the prediction and control of behavior. These approaches renewed interest in the empiricist tradition that emphasized learning experiences as the foundation of knowledge, rather than rationalist view that emphasized the importance of innate characteristics. Although initially resisted by most contemporaries, the behaviorist view gradually came to dominate American psychology for half of the twentieth century, changing the definition of the discipline from "the science of mental life" (James, 1890: p. 1) to "the science of human and animal behavior."

Within this behaviorist emphasis researchers differed in the type of behavior they investigated. Some pursued Watson's Pavlovian emphasis on associative, reflexive, respondent (Classical) conditioning. However, the emphasis eventually shifted to the study of purposive, goal-directed behaviors, which organisms voluntarily emit and which lead to consequences that influence future behavior. Edward Thorndike (1874–1949), a pioneer in the study of goal-directed behavior, used the term 'law of effect' in 1898 to emphasize the role of the consequences of behavior to explain its purposive aspects. In 1912, William McDougall (1871–1938) emphasized a behavioral perspective in studying purposive behavior, which he defined as spontaneous, rather than a response to a known stimulus, and which persists until the attainment of a goal. This emphasis on purposive, goal-directed behavior came to characterize the era of the learning theories in the USA, from the 1930s through the 1960s, which used nonhuman animals to

study learning, the primary mechanism by which organisms adapt to environmental change.

Three major approaches vied for dominance during this period, erecting theories of learning following the logical positivist approach to theoretical concepts (see below). Edwin Guthrie (1886–1959) remained close to Watson's respondent learning approach by attempting to explain purposive behavior in terms of the laws of associative learning; he depicted purposive learning as a response to the most recent stimuli associated with that response. Clark Hull (1884–1952) applied the model of Newton's physics to psychology, developing a psychological theory explaining purposive behavior in mechanistic terms. He emphasized the importance of biological drive as motivating behavior, with reduction of the drive serving to reinforce, or increase the probability of, the behavior that led to it. Edward Tolman (1886–1959) attempted to explain purposive behavior in behavioral terms, but he operationally defined concepts like purpose and cognition as intervening variables in goal-directed behavior. His theory sustained a cognitive emphasis that supported the resurgence of cognitive psychology in the 1960s.

The behaviorist perspective reached its zenith in the 1960s with B.F. Skinner's (1904–90) operant conditioning approach, which rejected the need for theories of learning and use of cognitive, or mentalistic, explanations of behavior. Instead, he analyzed the functional relationships among environmental situations, overt behaviors, and consequences, and how these three factors influenced the future probability of behavior. Using evolutionary theory as a metaphor, he described how, during an organism's lifetime, the environment selected its behaviors through the process of conditioning. Reinforcing environmental consequences strengthened (increased the probability of) behaviors, while other consequences decreased behavioral probability through punishment or extinction. Skinner's radical behaviorism became widely embraced in experimental psychology and also led to application in many fields of human services.

Influence of Logical Positivism

Throughout the behaviorist heyday, many psychologists in the USA, Europe, and elsewhere continued to pursue research on psychology's original topics such as sensation, perception, memory, problem-solving, and other cognitive topics. Although many investigators on these topics did not self-identify as behaviorists, most came to accept observable behaviors as the proper valid evidence for psychological processes, even if these behaviors consisted of responses to self-report questionnaires or scales. Based on the success of Newtonian physics, the methods of the natural sciences, grounded in the positivist belief in an absolute independent external reality accessible to human knowing through empirical research, emerged as psychology's dominant methodological approach. Twentieth-century psychologists reaffirmed natural sciences methodology and embraced the logical positivist argument of the Vienna Circle in the 1920s that legitimated the use of theoretical concepts as long as they were operationally defined. Eventually, logical positivism failed as a philosophy of science due to its self-referential incoherence (logical positivism states that meaningful statements require empirical verifiability, at least in principle; therefore, logical positivism itself cannot be meaningful, by its own criterion). However, despite strong criticism from within the field (Bakan, 1973), its adoption by psychologists, in conjunction with the positivist methodology of Newtonian physics and psychology's self-conscious focus on gaining scientific respectability, led to the primacy of research methodology, more than content, as the defining common identity of academic psychologists.

Subfields and Subspecialties

Gestalt Psychology

Although empirically based behaviorism dominated psychology research in America for the first half of the twentieth century, the Continental rationalist tradition remained active in Europe, particularly in the work of the German Gestalt psychologists, led by Max Wertheimer (1880–1943). Gestalt psychology continued to elaborate on the rationalist view of perception as an active process in which mental or brain processes structure and transform sensory data. Along with colleagues Wolfgang Köhler (1887–1967) and Kurt Koffka (1886–1941), Wertheimer provided persuasive support for the perspective that the tendency to perceive forms, structure, and patterns dominated the perception process more than particular sensory inputs, that the whole (perception) is greater than the sum of the parts (sensations) that generate it. Many Gestalt psychologists found a welcome home in America immediately before and after World War II, increasing interest in Gestalt principles, perception, and the active role of mental processes in America.

Social Psychology

Gestalt psychology also had an impact on the emerging subfield of social psychology. Several of the Gestalt psychologists who immigrated to the USA focused their work on applying the perspective to the influence of social factors, defined as the real or imagined presence of other people, on psychological processes. Kurt Lewin's (1890–1947) field theory pioneered the Gestalt approach to the study of personality and social behaviors and its application to motivation, conflict, and group dynamics. Lewin's and Koffka's student Tamara Dembo (1902–93) contributed to the study of frustration and aspiration, and Lewin's student Leon Festinger (1919–89) became well known for his work on social comparison and cognitive dissonance. Solomon Asch (1907–96) studied Gestalt psychology and taught at Swarthmore College with Köhler. He gained recognition for his work on how humans form impressions of others and for his research in conformity that demonstrated that groups can influence even obvious perceptions. Social psychology evolved into an active field that employed creative methodologies to study a variety of contemporary social topics that interested the psychologists of the time (Gergen, 1973).

Developmental Psychology

Darwin's theory also influenced the emerging field of developmental psychology by suggesting that functional psychological processes evolve in individuals across the life span, particularly during infancy, childhood, and adolescence. G. Stanley Hall (1844–1924), founder of the American

Psychological Association (APA), proposed that human development proceeds in a manner that mirrors the increasing complexity of organisms on the phylogenic scale, that 'ontology recapitulates phylogeny.' He built a strong developmental psychology program at Clark University that included Heinz Werner's (1890–1964) pivotal role in bringing the European, Kantian, intellectual traditions to America. Werner elaborated the orderly directionality of developmental changes in terms of a succession of structures that succeed each other (Glick, 1992). The Continental rationalist tradition also guided the work of the Swiss genetic epistemologist, Jean Piaget (1896–1980), whose constructivist cognitive approach greatly influenced developmental psychology and also sustained interest in cognitive processes during the behaviorist era. Piaget showed how a child's experience of the environment becomes more complex and adapted as the child articulates a cognitive schema in the process of biological maturation. These pioneering developmental themes of Werner and Piaget appear in a variety of subsequent developmental psychology models and approaches (Kegan, 1982).

Neuropsychology

Early-twentieth-century advances in studying the relationship between psychological and neurological processes continued to contribute to the evolution of psychological research. Karl Lashley (1890–1958) sought to identify the neurological bases of conditioned reflexes as studied by the Russian physiologists and championed by Watson's behaviorism. He reasoned that innate, instinctive reflexive responses to certain stimuli require an innate neurological structure, and thus conditioned associated responses to these stimuli might also come to have a specific neurological location. The term 'engram' referred to this hypothetical location of learning and memory, and Lashley devoted his career to attempting to find it. Ultimately, he failed to find a single location in the brain for specific learning and proposed that the brain operates as a unified whole rather than with specific physical links, a principle he called mass action.

Donald Hebb (1904–85) saw the newborn's brain as unstructured and undifferentiated, with organized connections among neurons occurring through experience. He surmised that sensory organs respond to environmental objects by firing a complex of neurons, which he called cell assemblies, as a result of reverberating neural activity that enabled separate neurons to establish connections while stimulated. He further suggested that the assemblies of neurons representing an environmental object become connected in a series of activities that he called phase sequences. These sequences come to represent complex trains of memories and thoughts. Hebb articulated the neurological level of connection by positing what came to be known as 'Hebb's rule' that neurons that fire together become wired together. These principles of mass action and cell assemblies influenced developments in cognitive science and neuroscience in the latter part of the twentieth century.

Psychology in Midcentury

Altman (1987) described the period of 1900–60 as a major era of consolidation of the discipline of psychology, within the various perspectives described above establishing the field's topics and defining its content. Methodologically, the emphasis on experimentation, quantification, and laboratory-based research unified the prominence of experimental methodology as the discipline's standard. By reaffirming the logical positivist perspective, the methodology supported operational definitions of theoretical concepts, the quest for causal relationships, and the 'discovery' of universal laws and principles of human and animal cognition and behavior.

Graduate students in psychology during this period typically received broad exposure to psychological theory, research, and content that led to their identification with the discipline as a whole. In sum, "psychology during the 1900–60 period displayed a general pattern of centripetality in research and theory, philosophy of science, graduate education, and organizational infrastructure. This centripetal pattern resulted in consolidation and unification of the discipline" (Altman, 1987: p. 1061). This sense of unification existed even though psychology had not generated an agreed-upon core lexicon, or shared paradigm (Kuhn, 1962), as was the case in other established scientific disciplines.

Late-Twentieth-Century Developments

In the latter half of the twentieth century, two interrelated themes influenced research into the questions and topics that characterized this unified discipline of psychology. The waning popularity of behaviorism and its emphasis on learned behavior influenced a resurgence of interest in cognition and invigorated the importance of nativist, biological explanations of psychological phenomena. Additionally, rapid technological improvements, which routinely stimulate advances in many scientific fields (Pickering, 1984, 1995), had an increasing impact on academic research on psychology's core questions and topics.

Resurgence of Cognitive Psychology and Cognitive Science

A symposium at MIT on information theory in 1956 sparked a revival of research in cognition within the context of the development of sophisticated computer technology, cybernetics, and information processing models. George A. Miller (1920–2012) demonstrated that humans can discriminate seven aspects of events and retain seven units of experience, and published his landmark text Psychology: The Science of Mental Life in 1962, reclaiming James' original definition of the discipline. Jerome Bruner (b. 1915) studied abstract thinking, concept learning, and the use of active cognitive strategies. Ulric Neisser (1928–2012) defined cognition as any processes that transform, reduce, elaborate, store, recover, and use sensory input, further clarifying this renewed approach to the topics that occupied early experimental psychology.

Subsequent developments in cognitive psychology focused on computer programs as a metaphor for the processes of the human mind, leading to the field of artificial intelligence, a branch of computer science. Englishman Alan Turing (1912–54) founded this field by asking whether a machine can actually think, creating his famous Turing test in which

participants attempt to consistently differentiate a human responder from that of a computer. The question of whether computers actually think like a human or only follow rules of program received further discussion by John Searle (b. 1932), who argued against the likelihood of valid artificial intelligence. By the mid-1970s, Neisser criticized the computer and information models of cognition as too sterile and argued that cognitive psychologists should study cognition as it naturally occurs in people's ordinary lives and how it functions in their purposeful activities. However, computer modeling remained the major methodology.

Toward the end of the twentieth century, an interdisciplinary field of cognitive science emerged, combining the work of psychologists with anthropologists, linguists, computer scientists, neuroscientists, and philosophers. An approach called connectionism surfaced as an active model in this field, attempting to provide a computer-based virtual model of how the cognitive and neurological system learns by studying the relationship between input and output in terms of Hebb's rule and Lashley's principle of mass action.

Neuropsychology, Neuroscience, and Evolutionary Psychology

Late-twentieth-century development of sophisticated neuroimaging measurement techniques such as functional magnetic resonance imaging and computed axial tomography scanning, along with advances in human genetics and electrophysiology, enhanced the progression of mapping human emotions and cognitions to specific neural areas, rapidly extending the earlier work of Lashley and Hebb. These developments led to emergence of the interdisciplinary field of neuroscience, including disciplines such as biology, linguistics, mathematics, computer science, and philosophy, as well as psychology, which studies neural circuitry and its relationship to psychological functions.

As we have seen, Darwin's theory of evolution influenced many, if not most, areas of psychology. Toward the latter part of the twentieth century, however, we see the development of a specific approach to psychology called evolutionary psychology. This perspective evolved from sociobiology, founded by Edward O. Wilson (b. 1929), which proposed that evolution has selected for humans with innate tendencies toward social behavior, language, creating cultures, social conventions, phobias, etc. The question of the relative strength of these innate tendencies versus the influence of culture and learning experiences generated a lively debate, with Wilson suggesting that nature gives us a 'long leash,' enabling flexible modes of adapting to changing environments, rather than a 'short leash' that strictly determined specific behaviors.

Evolutionary psychology regards human psychological processes as a collection of functionally specialized regulatory structures or circuits that organize how humans interpret experiences and create concepts and frameworks of meaning. This evolutionary perspective recognizes the universality of 'normal' human behavior through the study of natural competencies that all humans share. Leda Cosmides and John Tooby (1997) thus define psychology as a branch of biology that studies how brains develop programs to process information, emphasizing the brain as a physical system that functions as a computer and generates behavior appropriate to the environment. They regard the brain's neural circuitry as a complex system of specialized pathways that evolved through natural selection to assist in solving problems that the humans encountered over the course of evolutionary history. Both sociobiology and evolutionary psychology base their work on the assumption that we can understand psychological processes as selected for by their benefit in perpetuation of copies of genes into subsequent generations.

Psychology at the End of the Twentieth Century

Irwin Altman (1987) in the USA, Theo Herrmann (2009) in Germany, and Tommy MacKay (2001) in the United Kingdom, each in their own way, characterized the latter half of psychology's twentieth century, in contrast to the first half, as a time of centrifugal trends and discontinuity. They portray the field as a proliferation of specialty areas, loss of a shared common history (Fuchs and Viney, 2002; Samelson, 1999) and core of mutual beliefs, and a weaker identification of its members with the field as a whole. Graduate programs came to focus more on specialized areas, with each field developing its own curriculum and cohort of students, organizational structures, and separated physical quarters. Applied and professional psychology programs became distanced from the basic science of the field, and professional schools and psychotherapy training programs proliferated independently of academic research psychology.

Much of what had become the traditional content of psychology has been absorbed into the newly emerging interdisciplinary specialties of cognitive science and neuroscience (Gardner, 2009; Gentner, 2010), decreasing psychology's absolute claim to this territory (MacKay, 2001). The author's own graduate education exemplifies this trend. I completed my PhD in the Department of Psychology at the University of Rochester in 1971, with a major in clinical psychology and a minor in perception. In 1995, the Department of Psychology ceased to exist, as it split into two departments: the Department of Clinical and Social Sciences in Psychology (locus of my major field) and the Department of Brain and Cognitive Sciences (locus of my minor field).

We can also see this fragmentation reflected in the organization structure of the discipline in the United States. The APA originally primarily represented those involved in academic and basic research and only slowly admitted professional psychologists over its early developing years. By the 1980s, however, professional psychologists came to outnumber academics in APA, and it currently functions as an organization serving the interests of professional practitioners. This trend led to the establishment of an alternative organization in 1988, The Association for Psychological Science (APS), which focuses on research and the scientific aspects of the field. APS has embraced an international perspective and the inclusion of the interdisciplinary fields described above, sponsoring an international convention of psychological science in the Netherlands in 2015.

Although we might feel compelled to do so, we need not regard fragmentation, discontinuity, and centrifugal trends as harmful to the discipline. Rather, we can view them as reflecting an energetic period of change and reformulation that can imbue the discipline with new directions in methods and

theories. By regarding psychology as a relatively young discipline, even characterizing it as in a medieval period (Cromwell, 2010), we can see the state of the discipline in the beginning of the twenty-first century as providing intriguing opportunities for new ideas and formulations.

Challenges to Twentieth-Century Conventions

Although most mainstream academic and research psychologists maintain a commitment to the scientific goal of establishing general laws of human nature through empirical research and logical positivist theorizing, alternative approaches began to receive growing attention by the end of the twentieth century. Sometimes viewed as part of a broader postmodern movement and reflecting challenges to scientific absolutism spawned by Kuhn's (1962) critique of the correspondence theory of scientific truth, many psychologists have begun to question the prevailing view that scientific methods uncover objective, permanent truths. Instead, they suggest that humans play a central role in the construction of knowledge. A variety of approaches to psychology, including personal constructivism (Raskin, 2002), social constructionism (Gergen, 2009), contextualism (Hayes et al., 2001), hermeneutics (Martin and Sugarman, 1999; Slife and Christensen, 2013), Buddhism (McWilliams, 2014), and pragmatism (Fishman, 1999), emphasize the active responsibility of human psychological and social processes in generating ever-changing knowledge and the temporal embeddedness of these processes in historical, cultural, and language contexts. Albert Bandura's (2006) social cognitive approach also came to strongly embrace the active role of human agency in coevolution and creating unanticipated futures in a world of flux and change. Although not without criticism from those committed to conventional psychological models (Held, 2007), these perspectives suggest alternative models that may have promise for a new view of the field.

We might anticipate that as many of the topics that originally fell within psychology's twentieth-century domain migrate to interdisciplinary, biologically based fields, psychology may come to focus more on the processes by which people, personally and collectively, actively create knowledge and meaning, including the approaches to knowledge and meaning that we call science. Perhaps then, rather than viewing psychology as a branch of the natural sciences, we may come to see the natural sciences, the humanities, the arts, religion, philosophy, and other human undertakings as the subject matter of psychology.

This article is a revision of the previous edition article by J.O. Ramsay, volume 18, pp. 12416–12422, © 2001, Elsevier Ltd.

Abstract

Psychometrics is a scientific discipline concerned with the construction of measurement models for psychological data. In these models, a theoretical construct (e.g., intelligence) is systematically coordinated with observables (e.g., IQ scores). This is often done through latent variable models, which represent the construct of interest as a latent variable that acts as the common determinant of a set of test scores. Important psychometric questions include (1) how much information about the latent variable is contained in the data (measurement precision), (2) whether the test scores indeed measure the intended construct (validity), and (3) to what extent the test scores function in the same way in different groups (measurement invariance). Recent developments have focused on extending the basic latent variable model for more complex research designs and on implementing psychometric models in freely available software.

Definition

Psychometrics is a scientific discipline concerned with the question of how psychological constructs (e.g., intelligence, neuroticism, or depression) can be optimally related to observables (e.g., outcomes of psychological tests, genetic profiles, neuroscientific information). This problem is most often approached through the construction of measurement models, in which the construct of interest is represented as a latent variable that acts as a common determinant of a set of observable variables (Bollen, 2002; Sijtsma, 2011). Psychometrics is a highly interdisciplinary field, with connections to statistics, data theory, econometrics, biometrics, measurement theory, and mathematical psychology. Psychometricians may be involved in the design of psychological tests, the formalization of psychological theory, and the construction of data-analytic models. The latter activity has, in the past century, been the main focus of the discipline, especially through the development of test theory and associated latent variable modeling techniques. The main professional organization of psychometricians is the *Psychometric Society*, which publishes the journal *Psychometrika* and organizes the annual *International Meeting of the Psychometric Society*.

History

The birth of psychometrics is usually situated at the end of the nineteenth century, when Francis Galton set up the Antropometric Laboratory with the intention to determine psychological attributes experimentally. Among the first constructs of interest to be subjected to measurement were keenness of sight, color sense, and judgment of eye (Galton, 1884). Galton attempted to measure such attributes through a variety of tasks, recording performance accuracy as well as reaction times. In the early twentieth century, the interest in measuring human qualities intensified greatly when the United States implemented a program to select prospective soldiers using tests (the Army Alpha and Beta) that purported to measure a range of abilities deemed relevant for military performance. Such tests produced a great deal of data, which led to questions that inspired the birth of psychometric theory as we currently know it: how should we analyze psychological test data? Which properties determine the quality of a psychological test? How may we find out whether a test is suited for its purpose?

Two important properties of tests were almost immediately identified (Kelley, 1927). The first referred to the question of whether a test produced *consistent* scores when applied in the same circumstances. This question introduced the notion of *reliability*. In general, a measurement instrument is reliable to the extent that it yields the same outcomes when applied to persons with the same standing of the measured attribute under the same circumstances (e.g., to what extent does an IQ test produce the same score if administered to people with the same level of intelligence?). The second important question is whether the test measures what it purports to measure. This question defines the concept of *validity*. Although different views of validity exist (see later text), the textbook definition is that a measurement instrument is valid if and only if it measures what it should measure (e.g., an IQ test is valid if and only if it actually measures intelligence). The concepts of reliability and validity are still among the most important ones in the evaluation of psychological tests, although they have a very different status in psychometric theory. The definition of reliability is widely accepted, but the definition of validity is widely contested.

The development of reliability theory in the first half of the twentieth century culminated in the work of Lord and Novick (1968), who presented the currently accepted definition of reliability as a signal-to-noise ratio (the ratio of true score variance to observed score variance). The concept may be somewhat differently conceptualized in different theoretical frameworks (e.g., as measurement precision in latent variable theory (Mellenbergh, 1996) and as generalizability in generalizability theory (Cronbach et al., 1972)). However, in such cases Lord and Novick's definition typically follows as a special case, which indicates the consistency of the general psychometric framework. Reliability can, under appropriate assumptions, be estimated in various ways; for instance, from the correlation between two test halves, from the average correlation between test items, and from the correlation

between two administrations of the same test at different times. Strictly speaking, such reliability estimates signify properties of test scores rather than of tests themselves (e.g., administering the test to different populations will ordinarily lead to different values for reliability). Although some discussion may exist about how to optimally estimate reliability, or about which coefficient should be preferred in a given context (Sijtsma, 2009), there is little discussion about how to define reliability theoretically or on how to determine it empirically.

The opposite holds for validity. There are no widely accepted methods to determine whether a test is valid (or to estimate its degree of validity, for theories that conceptualize validity as a matter of degree). In fact, there is no agreement on what validity refers to (Borsboom et al., 2004; Lissitz, 2009; Sijtsma, 2011; Newton, 2012). These disagreements result from the fact that the question of whether a test measures what it purports to measure raises fundamental questions about the nature of psychological constructs themselves. For instance, can psychological constructs literally be measured, in the same way that length and mass are (Michell, 1999)? If not, what notion of measurement should be invoked? Should psychological constructs be given a realist interpretation, or are they merely summaries of data (Borsboom, 2005; Cronbach and Meehl, 1955; Trout, 1999)? Does it make sense to talk about the validity of tests at all, or should we rather talk about the validity of interpretations of test scores or of uses of test scores (Newton, 2012)? Should the societal consequences of test use be counted in the evaluation of validity (Messick, 1989)? Perhaps the only conclusion about validity that is widely accepted is that it is the most problematic among the psychometric concepts.

It is an interesting fact of scientific history that psychometric theory and practice developed largely in the absence of definitive answers to these fundamental questions. Perhaps as a result of the inability to come to grips with the slippery constructs of psychological science, psychometrics instead took its lead from statistics and from general ideas on how measurement should be conceptualized. In doing so, it became a largely technical discipline, which identified as its main task the construction of measurement models for psychological data. Usually, such models contain a 'stand-in' for the psychological construct to be measured (e.g., the expectation of the observed scores – the 'true score' – or a latent variable that is assumed to 'underlie' the responses to test items); they do not, however, contain psychological theory.

Although the detachment of modeling techniques and substance matter is occasionally lamented in psychometric circles, it is undeniable that the statistical models developed along statistical, data-analytic lines define some of the most important contributions of psychometric theory to science in general: classical test theory (Lord and Novick, 1968), latent class analysis (Lazarsfeld and Henry, 1968), the congeneric model (Jöreskog, 1971), the modern test theory models of Rasch (1960) and Birnbaum (1968), and the nonparametric item response models (Mokken, 1971). After these models had been constructed, the development of software to fit and estimate them became one of the main topics of psychometric research, and psychometricians played a leading role in the development of estimation algorithms (e.g., Bock and Aitkin, 1981), model fit tests (Andersen, 1973), software for test analysis (Zimowski et al., 1996; Thissen, 1983; Wilson et al., 1991; Bowler et al., 2007), and general latent variable modeling (e.g., Jöreskog and Sörbom, 1974; Muthén and Muthén, 1998; Bentler, 2000; Arbuckle, 2010; Vermunt and Magidson, 2000). This development took place during the last three decades of the twentieth century, at the end of which most of the basic psychometric models could be estimated and fitted.

Main Concepts of Standard Psychometric Theory

Psychometric measurement models relate a latent structure to a set of observed variables by mapping positions in the latent structure to distributions or densities of the observed variables. This is usually done by specifying the conditional distribution function of the observables, given the latent structure. Thus, the general framework can be thought of in terms of a simultaneous regression of the observed variables on a latent variable or a set of latent variables. Many different models can be derived from this idea through variations on (1) the form of the latent structure (e.g., a continuous line or a set of latent classes), (2) the form of the regression function (e.g., a step function or a logistic function), and (3) the distribution or density appropriate to the observations (e.g., a binomial distribution or a normal density). For instance, if the latent structure is a unidimensional continuum, the regression function is linear, and the observables follow a normal density, the resulting model is the linear common factor model (Jöreskog, 1971); if the latent structure is a unidimensional continuum, the regression function is logistic, and the observables follow a binomial distribution, we get the two-parameter logistic model (Birnbaum, 1968); and if the latent structure is categorical and the observed variables are binary, we obtain the latent class model (Lazarsfeld and Henry, 1968). Mellenbergh (1994b) provides a systematic overview of the connections between these and other models.

The latent structure is generally viewed as a representation of the construct to be measured (e.g., intelligence), while the observed scores typically represent concrete behavioral responses (e.g., answers to items in an IQ test). As a whole, the psychometric model thus coordinates the correspondence between observational and theoretical terms, and in that sense is a measurement model. It is important to note that the notion of measurement intended here is broad and covers the entire spectrum from categorical unordered models to quantitative continuous models. Thus the meaning of the term 'measurement' is not limited to the classical interpretation of the term, which implies quantitative continuous structure (Michell, 1986), although models that are consistent with stricter interpretations may be derived from the general model as a special case (e.g., Rasch, 1960). Thus, the psychometric model is a measurement model in the sense that it coordinates theory with observation, but not in the sense that it assumes that human behavior can be successfully analyzed in terms of quantitative laws.

Measurement precision. Reliability relates to the psychometric model via the concept of measurement precision. The measurement precision of test scores is inversely related to the

variance of the observed scores conditional on a given position in the latent structure (Mellenbergh, 1996). Thus, the higher the variance of the conditional distribution of the observables, the lower the measurement precision of the observables. Note that measurement precision may, but need not, be identical for different positions of the latent structure. For instance, in the linear factor model, which has homoscedastic residuals, measurement precision is identical for all values of the latent variable; in contrast, in the Rasch (1960) model, it is highest for the latent position where the logistic regression of the observable has its inflection point and lower for positions father away from that point; note also that, at the point where this curve has its lowest measurement precision, it yields maximal information. The reliability of test scores, as proposed in classical test theory (Lord and Novick, 1968), is an unconditional index of measurement precision that can be straightforwardly derived from the conditional definition (Mellenbergh, 1996).

Item Response Theory. If the observed variables are responses to test items (e.g., items in an IQ test), then the measurement model falls under the scope of item response theory (IRT), a subfield of psychometrics that has come to play an important role in the analysis of educational tests. In IRT, the function that specifies the regression of the observed variables on the latent structure is known as an item characteristic curve (ICC). Usually, IRT models assume a unidimensional and continuous latent structure, which means the ICC is a smooth curve as in Figure 1. Because items in educational testing are typically scored dichotomously (1: correct, 0: incorrect), the ICC is bounded from above and from below, and hence is often modeled using a nonlinear function. The slope of the ICC at a given point on the latent scale is proportional to the ability of the item to discriminate between positions above and below that point, and thus determines the amount of information that the item yields at that point. Plotting the item information against the latent variable then gives the item information function (IIF).

Figure 1 Item response theory relates the probability of a correct response to an item to a continuous latent variable through item characteristic curves (ICCs). When ICCs are parallel, as in this figure, items located further to the right have a lower probability of a correct item response for a given level of the latent variable and are typically interpreted as more difficult.

Adaptive testing. The IIF plays an important role in psychometrics because it can be used to regulate the selection of items. This idea forms the basis for adaptive testing (Van der Linden and Glas, 2000), a strategy of adaptively assembling tests that has become increasingly important with the advent of computerized test administration. In adaptive testing, items are administered sequentially and selected for administration adaptively, i.e., on the basis of the previous item responses of the respondent. This typically works as follows: at each point in the item administration process, examinee ability (the position in the latent structure) is estimated on the basis of the item responses given so far. The next item to be administrated is then chosen on the basis of the slope of the IIF at the estimated examinee ability, so that the administered items yield optimal information. In this way, tests can be shortened without affecting reliability.

Measurement invariance. Test scores are often used to select individuals (e.g., in job selection, student placement). Typically, these selection processes operate on populations that are heterogeneous with respect to background variables like sex and ethnicity. In these cases, considerations of fairness suggest that the test should function in the same way across different subpopulations, in the sense that it should not produce systematic bias in the test scores against a certain group. Such bias may, for instance, arise when an IQ test contains questions that are easier for test takers with a specific background regardless of their intelligence level. This may, for instance, occur if the test contains general knowledge questions that draw on a specific cultural background, so that they are more difficult for ethnic minorities for reasons independent of intelligence level. The concept of measurement invariance (Mellenbergh, 1989; Meredith, 1993) formalizes this idea and allows for testing it against empirical data.

Alternative psychometric models. Although the latent variable model is the primary race horse of current psychometrics, it is not the only available model to connect theoretical terms to observations. An important alternative in the psychometric literature concerns multidimensional scaling (MDS). MDS is a psychometric tool to infer the number of underlying dimensions in proximity data, i.e., data consisting of measures of similarity among pairs of stimuli (e.g., the degree in which different facial expressions are judged to be similar). Depending on whether the measurement scales of the similarity measures are either continuous or ordinal, one speaks of metric MDS (Torgerson, 1952) or nonmetric MDS (Shepard, 1962), respectively. In MDS, individual differences are taken into account by weighting the underlying dimensions differently across subjects (Carroll and Chang, 1970). By doing so, each subject receives a different weight for each dimension indicating which dimensions are more important for a subject in deciding which stimuli are similar. These weights enable identification of different subtypes of subjects. An important instance of MDS with individual differences is unfolding analyses, which is suitable for preference data. In unfolding analyses (Coombs, 1964), each subject is assumed to have an ideal point on the dimensions underlying the preference data. When a given stimulus is close to the subjects ideal point, that stimulus is preferred more.

In addition to MDS, other possibilities to make the connection between theory and data are by (1) representing the

construct as a common effect of the observed variables (Bollen and Lennox, 1991), (2) taking the construct to be a universe of behaviors, of which the observables are assumed to be a sample (Cronbach et al., 1972; McDonald, 1999), and (3) interpreting the construct as a causal system in which the observables influence each other (Cramer et al., 2010).

Recent Developments

The past couple of years, advances in psychometrics have mainly focused on extensions of the traditional measurement models to deal with more complex situations. Important extensions include the incorporation and development of multilevel and random effects structures in IRT models (Fox and Glas, 2001), factor models (Rabe-Hesketh et al., 2004), and latent class models (Lenk and DeSarbo, 2000). In these models, item parameters – considered fixed effects in the traditional measurement models – may themselves become random variables. This enables psychometric analyses of nested data, which are common in large-scale assessments. These extended models have been formulated within integrated frameworks that include the different models as special cases (Moustaki and Knott, 2000; Skrondal and Rabe-Hesketh, 2004).

Other extensions were motivated by the increasing popularity of computerized test administration. This causes response times to become available to the researcher in addition to the ordinary responses. Various suitable models have been proposed including models in which response times are modeled as collateral information (Van der Linden, 2007, 2009; Van Breukelen, 2005) or as manifestation of the underlying decision process (Tuerlinckx and De Boeck, 2005; Van der Maas et al., 2011).

Furthermore, recent advances in computer technology enabled more refined estimation techniques and model fit assessment, particularly for multidimensional IRT models (Béguin and Glas, 2001; Reckase, 2009), factor analyses of non-normal and categorical data (Satorra and Bentler, 2001; Molenaar et al., 2012), cognitive diagnosis models (Junker and Sijtsma, 2001; De la Torre and Douglas, 2004), unfolding analyses (Busing et al., 2005), and nonlinear factor models (Klein and Moosbrugger, 2000; Lee and Zhu, 2002).

On the conceptual side, three discussions have dominated the psychometric literature of the past decade. One concerns the status of psychometric measurement models and the relation between psychometrics and psychology (Michell, 1999; Borsboom, 2006). A second important discussion concerns the usefulness of Cronbach's alpha as a measure of reliability, which has been forcefully contested (Zinbarg et al., 2005; Sijtsma, 2009). Third, the proper definition of validity remains a contentious topic that continues to generate debate (Lissitz, 2009; Newton, 2012).

With respect to psychometric software, recent developments have mainly been inspired by the rise of the open source statistical software program R (R Development Core Team, 2012). This program enables psychometricians to develop their own model estimation packages and share these with other researchers. This trend is illustrated by two recent special issues of the *Journal of Statistical Software* (2007, 2012) that focused exclusively on psychometrics in R. Among the most popular R packages for psychometric analyses are *ltm* (Rizopoulos, 2006) and *eRm* (Mair and Hatzinger, 2007), which can fit various IRT models to data; *mokken* (Van der Ark, 2012), which may be used to fit nonparameteric IRT models to data; *sem* (Fox, 2006) and *lavaan* (Rosseel, 2012), which enables structural equation modeling; *smacof* which involves MDS (De Leeuw and Mair, 2009); and *qgraph* (Epskamp et al., 2012), which produces network visualizations of psychometric data and models. In addition, the *OpenMx* package (Boker et al., 2010) is a more general R package that can be used to fit various (extensions of) parametric models, including advanced possibilities like mixtures and joint modeling of discrete and continuous data.

Psychometrics: Classical Test Theory

James Algina, University of Florida, Gainesville, FL, USA
Hariharan Swaminathan, University of Connecticut, Storrs, CT, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The principal developments in classical test theory are presented, including the classical true score model, the observed score random variable, the true score, the error score random variable, the reliability coefficient, the standard error of measurement, the effect of test length on statistical properties of test scores, single-administration coefficients of reliability, and models for degrees of equivalence among test scores.

Classical Test Theory

Assessment, evaluation, and research in social and behavioral sciences are typically based on the responses to stimuli presented to research participants or on observations of the participants in laboratory or natural settings. The research participants are more often than not people, but may be animals or some other entities such as schools. For simplicity we will refer to people in the following. The responses or observations are usually used to create scores on one or more variables. We will refer to the procedures for collecting the data as tests and the resulting scores as test scores. Following is a list of tasks, adapted from Gulliksen (1950), involved in constructing, scoring, and evaluating tests:

1. Writing and selecting the test items or specifying the behaviors to be observed and the procedure for making the observation.
2. Assigning scores to participant. Scaling and linking procedures are sometimes used to conduct this task.
3. Assessing the degree of accuracy of the test scores. Methods for assessing reliability and measurement error variance are used to address this task.
4. Assessing the degree to which interpretations of test scores and/or decisions based on the test scores are warranted. Methods for investigating validity are used to address this task.

Test theory comprises the statistical models used in accomplishing these tasks, the procedures for estimating the models, and the experimental designs used for collecting data to estimate the models. The body of literature on each is quite large, even when limited to classical test theory (CTT). In this article we focus primarily on statistical models for reliability and measurement error variance. One implication of this focus is that estimation of reliability and measurement error variance is, for the most part, not addressed. Developments that are not addressed in this article can be traced in the four editions of *Educational Measurement* (Lindquist, 1951; Thorndike, 1971; Linn, 1989; Brennan, 2006). Changes in the conception of validity can also be traced in the *Standards for Educational and Psychological Testing* published in 1954, 1966, 1974, 1985, and 1999. Algina and Penfield (2009) provided a brief account of these changes. See Borsboom (2005; 2006) for critiques of CTT and current conceptions of validity.

Classical Test Theory

CTT is a branch of test theory that is identified in contrast to modern approaches to test theory. According to Traub (1997) (1) the origins of test theory are in three intellectual achievements in the eighteenth and nineteenth centuries: "A recognition of the presence of errors in measurements, a conception of that error as a random variable, and a conception of correlation and how to index it" (p. 8) and (2) the first publication in CTT was Spearman (1904). Lord (1952), in a monograph on item response theory (IRT), referred to 'the classical theory of error' and distinguishes conclusions implied by that theory from conclusions implied by IRT, a prominent modern test theory. Du Mas (1956) referred to the 'newer theory of latent classes' in contrast to CTT. Loevinger (1957) wrote "The central concepts of classical test theory are reliability and validity" (p. 636) and commented on revisions to the concept of validity: "The rather sudden appearance of the term 'construct validity' indicates that the second concept of classical test theory is undergoing criticism and revision" (p. 636). In 1963, Cronbach, Rajatanam, and Gleser referred to the 'classical theory of reliability' to distinguish it from generalizability theory, a more general approach to assessing measurement reliability.

Although new developments in CTT are still being made, it is fair to say that seminal work took place between 1904 and the mid-1970s. Brown and Thompson (1921) provided comprehensive presentation of early work in the field. Thurstone (1932) was also influential. Gulliksen (1950) provided summary of results in CTT developed in the first half of the twentieth century. Lord and Novick (1968) summarized results in CTT as well as modern approaches to test theory. Koutsopoulos (1962; 1964) provided an axiomatic approach to the CTT as did Novick (1966). The books by McDonald (1999), Osterlind (2010), and Raykov and Marcoulides (2010) provide reviews of elements of both classical and modern test theory.

Classical True Score Model

A central idea of CTT is the classical true score model (CTSM), which expresses the observed score on a measurement (X) as the sum of a true score (T) and an error score (E):

$$X = T + E$$

There are different conceptions of the true score. For example, Lord and Novick (1968: p. 28), present three conceptions. In the conception they favor, when a particular person is measured at a particular point in time by using a particular test, there is a distribution of possible outcomes for the person's measurement. This distribution, which Lord and Novick call a propensity distribution, arises due to the random processes that operate in measuring a person's fluctuations of memory and attention in cognitive tests. The true score for a person is the mean of the propensity distribution. Consequently, the observed score for a person is an unbiased estimate of the person's true score. Note that the calculation of the true score is not possible unless the propensity distribution is known, which is typically not true. Therefore the true score variable is called a latent (i.e., hidden) variable. In passing we note that the term 'true score' does not imply that it would necessarily be a useful score for the assessment, evaluation, or research purposes for which the data were collected. For example, suppose a university develops a test to select applicants for admission. If true scores on the test do not accurately predict grade point average scores, then the true scores may not be useful for admission decisions. The error score is the difference between the observed score and the true score: $E = X - T$. Because E is the difference between a variable (X) and a constant (T), the propensity distribution for the error score is the same as the propensity distribution for the observed scores except that the mean of the former distribution is zero rather than T. The error score is also a latent variable. The variance of the propensity distribution is the person-specific error variance which we denote as $\sigma^2_{E_j}$ to emphasize that it applies to person j.

Principal Statistical Results Used in CTT

Although T and E are defined in terms of the propensity distribution, in CTT the means, variances, covariances, and correlation coefficients of X, T, and E over a population of persons are usually of interest and the principal results of CTT are expressed in terms of these parameters. Derivation of the principal results of CTT depends on four results from multivariate statistics. Although these results are presented below in terms of observed variables, they apply as well to true and error variables.

1. The correlation coefficient for two variables is the covariance between the variables divided by the product of the standard deviation of each of the variables. For example, if X and Y are two variables then $\rho_{XY} = \sigma_{XY}/(\sigma_X\sigma_Y)$, where ρ denotes the correlation, σ with two subscripts (i.e., σ_{XY}) is a covariance, and σ with a single subscript (e.g., σ_X) is a standard deviation. Rearranging the formula for the correlation coefficient results in $\sigma_{XY} = \rho_{XY}\sigma_X\sigma_Y$. The correlation of a variable with itself is equal to one and therefore $\sigma_{XX} = 1\sigma_X\sigma_X = \sigma^2_X$ the covariance of a variable with itself is the variance of the variable.
2. If X_1 to X_K are K variables, the mean of the linear composite $\tilde{X} = X_1 + \cdots + X_K$ is the sum of the means of the variables: $\mu_{\tilde{X}} = \mu_{X_1} + \cdots + \mu_{X_K}$. The ellipsis between the plus signs denotes all of the intervening terms. The variance of a linear composite is the sum of the variances of the variables plus twice the sum of the covariances between the variables: $\sigma^2_{\tilde{X}} = \sigma^2_{X_1} + \cdots + \sigma^2_{X_K} + 2(\sigma_{X_1X_2} + \cdots + \sigma_{X_{K-1}X_K})$.
3. The covariance between one linear composite and a second is the sum of the covariances of each variable in the first composite with each variable in the second. If $\tilde{Y} = Y_1 + \cdots + Y_J$, then

$$\sigma_{\tilde{X}\tilde{Y}} = \sigma_{X_1Y_1} + \sigma_{X_1Y_2} + \cdots + \sigma_{X_1Y_J} + \sigma_{X_2Y_1} + \sigma_{X_2Y_2} + \cdots + \sigma_{X_2Y_J} + \cdots + \sigma_{X_KY_1} + \sigma_{X_KY_2} + \cdots + \sigma_{X_KY_J}$$

In the special case of the covariance between one variable and a sum of variables, the covariance is the sum of the covariances of the variable with each of the variables in the sum. For example,

$$\sigma_{\tilde{X}Y_1} = \sigma_{X_1Y_1} + \cdots + \sigma_{X_KY_1}$$

4. The regression relationship between two variables is $Y = \mu_Y + (\sigma_Y/\sigma_X)\rho_{XY}(X - \mu_X) + \varepsilon$. The predicted value of the Y variable is $\hat{Y} = \mu_Y + (\sigma_Y/\sigma_X)\rho_{XY}(X - \mu_X)$.

Principal Implications of the CTSM

Mean of the Observed Score Variable

From $X = T + E$, we find $\mu_X = \mu_T + \mu_E$. Because the average error score is zero for each person, the average error score is zero over a population of persons and, therefore $\mu_X = \mu_T$. Because a sample mean is an unbiased estimator of a population mean, the sample mean of an observed score is an unbiased estimator of the population true score mean. That is, the average observed score provides correct information about the average true score.

Variance of the Error Score Variable

As noted earlier, the error variance $\sigma^2_{E_j}$ is the error variance for person j. The variance of E over a population of persons is the average value of $\sigma^2_{E_j}$ for that population and is denoted by σ^2_E.

Variance of the Observed Score Variable

An important feature of the distribution of X, T, and E is the relationship between T and E. Figure 1 is a plot of error scores against true scores that conform to the CTSM. The plot, which is for a sample size of 1000, indicates that the correlation of the error and true scores is near zero. In fact the sample correlation is 0.005. It can be shown that the CTSM implies that the population correlation of true and error scores, denoted by ρ_{TE}, is exactly zero. From $X = T + E$, $\sigma^2_X = \sigma^2_T + \sigma^2_E + 2\sigma_T\sigma_E\rho_{TE}$. Because $\rho_{TE} = 0$, $\sigma^2_X = \sigma^2_T + \sigma^2_E$. That is, under the CTSM, observed score variance is equal to true score variance plus error score variance.

Reliability Coefficient

Consider a hypothetical situation A in which $\sigma^2_T = 0$; then all persons have the same true score, $\sigma^2_X = \sigma^2_E$, and all differences

Figure 1 Plot of Error Scores vs True Scores.

among observed scores are due to errors of measurement. Any use of the observed scores to compare different people is fatally flawed because the differences are merely due to random errors of measurement and should be ignored. Now consider a hypothetical situation B in which $\sigma_E^2 = 0$; then $\sigma_X^2 = \sigma_T^2$, all differences among observed scores are due to true score differences: any comparison of observed scores for different people is equivalent to comparison of true scores and is not influenced by measurement error. Considering these observations, a useful parameter in CTT is the ratio of true score variance to observed score variance: σ_T^2/σ_X^2. This ratio is called the reliability coefficient. In situation A, the reliability coefficient is zero, which indicates that any comparison of observed scores will be problematic. In situation B, the reliability coefficient is one indicating that measurement error does not influence the comparison of scores. As these examples suggest, reliability coefficients near one are desirable whenever test scores are used to compare individuals. It can be shown that the correlation between the observed and true score variables is $\rho_{XT} = \sigma_T/\sigma_X$, which is called the index of reliability. Squaring the index gives $\rho_{XT}^2 = \sigma_T^2/\sigma_X^2$: in the CTSM the squared correlation between the observed and true score variables is equal to the reliability coefficient. Further, using $\sigma_X^2 = \sigma_T^2 + \sigma_E^2$, we find that $\rho_{XT}^2 = \sigma_T^2/(\sigma_T^2 + \sigma_E^2)$.

Effect of Heterogeneity on Reliability

Suppose an achievement testing company has developed a reading comprehension test that can be used with children in the following grade range: beginning of second grade to the end of third grade. One researcher administers the test to children who are beginning second grade and another administers the test to children who are either beginning second grade or finishing third grade. We would expect the true score variance to be larger for the second group because the mixed-grade group is likely to have more variation in reading comprehension than does the single-grade group. For which group of children will the reliability coefficient likely be larger? Suppose it is known that the error variance is unaffected by the grade of the children, then $\rho_{XT}^2 = \sigma_T^2/(\sigma_T^2 + \sigma_E^2)$ indicates that reliability will be larger for the children in the mixed-grade group because true score variance is likely to be larger for that group. As this example illustrates, reliability is a function of the heterogeneity of the individuals being measured and therefore is not solely a property of the test itself. For this reason, we should refer to reliability of test scores, rather than reliability of the test.

Standard Error of Measurement

The standard error of measurement is the standard deviation of the error scores: σ_E. To a rough approximation 95% of the error scores fall in the interval $[-2\sigma_E, 2\sigma_E]$. Thus, the standard error of measurement provides information about how large the error scores are likely to be. Suppose a psychologist administers a self-esteem instrument comprising ten 7-point items that are scored 1–7. If the score on the test is the sum of the item scores, the potential range of scores is then 10–70. If $\sigma_E = 1$, the psychologist knows that error scores tend to be quite small, particularly in comparison to the possible range of observed scores. Using $\rho_{XT}^2 = \sigma_T^2/\sigma_X^2$ and $\sigma_X^2 = \sigma_T^2 + \sigma_E^2$, it can be shown that $\sigma_E = \sigma_X\sqrt{1 - \rho_{XT}^2}$. Thus if we know the reliability coefficient, we can calculate the standard error of measurement. CTT methods have been developed to estimate the standard error of measurement for a particular person and for all persons with a particular observed score. See Feldt and Qualls (1996) for a method and literature review.

Correction for Attenuation

Spearman (1904) was motivated by a concern that measurement error attenuates the correlation between scores on two variables. In learning goal theory, a mastery goal refers to a goal of learning material for the sake of learning it. Educational

psychologists have been interested in the relationship between mastery goals and achievement test scores. Let X denote mastery goals and Y denote achievement and assume that measurements of each conform to the CTSM: $X = T_X + E_X$ and $Y = T_Y + E_Y$. In addition assume that the error score variables are not correlated. Applying the definition of the correlation coefficient to the true score variables and using the definition of the reliability coefficient, it can be shown that $\rho_{XY} = \rho_{T_X T_Y}\rho_{XT_X}\rho_{YT_Y}$. Because an index of reliability must be between 0 and 1, the equation shows that if at least one of the indices is smaller than 1, the correlation between the observed score variables must be attenuated. That is, the correlation between the observed score variables must be closer to zero than is the correlation between the true score variables.

Estimated True Score

The estimated true score is given by $\widehat{T} = \mu_X + \rho^2_{XT}(X - \mu_X)$, where $\widehat{T}$ is the estimated true score. This equation is derived by considering the linear regression relationship between T and X. The equation shows that if the reliability coefficient is zero, the estimated true score for each person in the population is equal to the observed score mean. This is appropriate because when the reliability coefficient is zero, all differences among observed scores are due to errors of measurement and the differences should be ignored. The equation also shows that if the reliability coefficient is 1, $\widehat{T}$ is equal to the observed score. Again this is appropriate because when the reliability coefficient is 1, the observed score is equal to the true score. The estimated true score has two sources of error as an estimate of T. First, when the reliability coefficient is between 0 and 1, the estimated true score is a biased estimator of the true score. By contrast the observed score is an unbiased estimator. Thus bias favors the observed score over the estimated true score. Second, the variance of $\widehat{T} - T$, the error in using $\widehat{T}$ as an estimate of T, is not larger than the variance of $E = X - T$, the error in using X as an estimate of T. Error variance favors the estimated true score. These two sources of error can be combined in a parameter known as the mean square error (MSE). The MSE for $\widehat{T}$ cannot be larger than the MSE for X, but can be smaller. Using the MSE as a criterion for picking an estimator, $\widehat{T}$ should be used. In practice $\widehat{T}$ is used infrequently if at all. There are two reasons. First, $\widehat{T}$ and X are perfectly correlated, so for many purposes it is irrelevant which is used. Second, if X is larger than its mean then $\widehat{T} < X$ and if X is smaller than its mean then $\widehat{T} > X$. Using the estimated true score requires explaining why more capable examinees are penalized and less capable examinees are advantaged when estimated true scores are used.

The estimated true score given above may be expressed as $\widehat{T} = \rho^2_{XT}X + (1 - \rho^2_{XT})\mu_X$. This form was first given by Kelly (1942). In recent years, this formula for the estimate of true score has been recognized as the prototype of the Bayes (or empirical Bayes) procedure for estimating a random variable (Novick and Jackson, 1974).

Parallel Measurements Model

Much of the early development in CTT was based on the parallel measurements model (PMM). The PMM concerns two or more measurements that conform to the CTSM. The PMM assumes that (1) each participant has the same true score on the measurements:

$$X_k = T + E_k$$

where the subscript indicates the kth of K measurements, (2) the error score variance is equal for all tests, and (3) error score variables are uncorrelated for all pairs of tests. Based on these assumptions and using the statistical results presented above, it can be shown that the following are equal for all K measurements (1) true score means, (2) observed score means, (3) true score variances, (4) error score variances, (5) observed score variances, (6) reliability coefficients, and (7) the correlation coefficient of each of the parallel measurements with any other variable, a variable we denote as Y. These equalities imply that parallel measurements are interchangeable. The equalities are summarized in Table 1 and compared to equalities that can be derived under alternative measurement models. Derivation of (7) assumes that Y conforms to the CTSM and that the error score variable for Y is uncorrelated with the error score variables for each of the parallel measurements.

Correlation Between Parallel Measurements

An important implication of the PMM is that $\rho_{X_k X_{k'}} = \sigma^2_T/(\sigma^2_T + \sigma^2_E)$: the correlation between two parallel measurements is equal to the reliability for each measurement. Assuming parallel measurements can be identified, this provides a basis for using observed score variables to estimate the reliability coefficient and the standard error of measurement. If the measurement error variables for X_k and $X_{k'}$ are not uncorrelated then $\rho_{X_k X_{k'}} = (\sigma^2_T + \sigma_{E_k E_{k'}})/(\sigma^2_T + \sigma^2_E)$ and may be larger or smaller than the reliability coefficient.

Effect of Test Length

Let $\tilde{X} = X_1 + \cdots + X_K$. The variable $\tilde{X}$ can be thought of as the result of using a longer test than any one of the K tests which result in the variables $X_1,\ldots,X_K$, which are assumed to be parallel. Let parameters for the longer test be denoted by using $\tilde{X}$,$\tilde{T}$, and $\tilde{E}$ subscripts and parameters for any one of the parallel measurements be denoted by using X, T, and E subscripts. The following are the effects of lengthening the test (1) true score mean: $\mu_{\tilde{T}} = K\mu_T$, (2) observed score mean: $\mu_{\tilde{X}} = K\mu_X$, (3) true score variance: $\sigma^2_{\tilde{T}} = K^2\sigma^2_T$, (4) error score variance: $\sigma^2_{\tilde{E}} = K\sigma^2_E$,

Table 1 Summary of equality features of five measurement models

Equality	*PMM*	*EPMM*	*TEMM*	*ETEMM*	*CMM*
Observed score means	Yes	No	Yes	No	No
True score means	Yes	No	Yes	No	No
Observed score variance	Yes	Yes	No	No	No
True score variance	Yes	Yes	Yes	Yes	No
Error score variance	Yes	Yes	No	No	No
Reliability coefficient	Yes	Yes	No	No	No
Correlation with criterion variable	Yes	Yes	No	No	No

PMM, parallel measurements model; EPMM, essentially parallel measurements model; TEMM, tau-equivalent measurements model; ETEMM, essentially tau-equivalent measurements model; CMM, congeneric measurements model.

(5) observed score variance: $\sigma^2_{\tilde{X}} = K\sigma^2_X[1 + (K-1)\rho^2_{XT}]$, (6) reliability: $\rho^2_{\tilde{X}\tilde{T}} = K\rho^2_{XT}/[1 + (K-1)\rho^2_{XT}]$, and (7) correlation with a criterion variable, denoted by Y: $\rho_{\tilde{X}Y} = \sqrt{K\rho^2_{XY}/(1 + (K-1)\rho^2_{XT})}$.

Generalized Spearman–Brown Formula

A comparison of the formulas in (3) and (4) in the preceding paragraph shows that, as a test is lengthened, the true score variances increase more rapidly than the error score variances. As a result the reliability of the scores on the longer test is larger than the reliability for the scores on the shorter tests. The effect of test length on reliability is summarized by the formula in (6), which is known as the generalized Spearman–Brown formula. A few calculations with example values of ρ^2_{XT} and K will show that, provided that $\rho^2_{X_kT}$ is between 0 and 1, (1) the reliability of scores on $\tilde{X}$ is larger than the reliability of scores on any one of the parallel measurements and (2) the effect of lengthening the test is larger when the $\rho^2_{X_kT}$ is smaller. However, these conclusions may not be correct if the error score variables are correlated for any of the parallel measurements.

Effect of Test Length on Criterion-Related Evidence of Validity

The correlation coefficient of a test with another variable is often called criterion-related evidence of validity for the test. For example if a company wants to use a test to select salespeople, the correlation of scores on the test with sales figure (i.e., the criterion) is criterion-related evidence of the validity. The formula in (7) shows the correlation of the longer test as a function of the number of parallel measurements, the correlation of each of these measurements with the criterion variable, and the reliability coefficient for each of the parallel measurements. Lengthening the test increases the correlation with the criterion. The impact of lengthening the test is larger when the reliability of the parallel measurements and the correlation of the parallel measurements with the criterion are smaller. The formula can be misleading if the error score variable for Y is correlated with the error score variables for one or more of X_1–X_K.

Reliability from a Single Administration of a Test

Suppose a test can be split into two half-tests that can be scored independently. For example, a test comprising 20 items could be split into two 10-item half-tests. Denote scores on the test as $\tilde{X}$ and on the half-tests as X_1 and X_2. Then $\tilde{X} = X_1 + X_2$. Assume the half-tests yield parallel measurements. Then the correlation coefficient for X_1 and X_2 is the reliability coefficient for each and we can use the generalized Spearman–Brown formula with $K = 2$ to express the reliability coefficient for $\tilde{X}$: $\rho^2_{\tilde{X}\tilde{T}} = 2\rho^2_{XT}/[1 + \rho^2_{XT}]$. This simplified formula is the Spearman–Brown formula and provides a method for computing the reliability coefficient for a test without requiring administration of more than one test. It is an example of a single-administration coefficient for test reliability. An alternative to the generalized Spearman–Brown formula is coefficient alpha: $\alpha = [K/(K-1)][1 - (\sigma^2_{X_1} + \cdots + \sigma^2_{X_K})/\sigma^2_X]$. Cronbach (1951) provided the name coefficient alpha, but noted that it has a long history in test theory dating back to Kuder and Richardson (1937), who derived it for the special case of dichotomously scored items. It can be shown that under the PMM, the generalized Spearman–Brown formula and the formula for coefficient alpha are equivalent. If $K = 2$ then $\alpha = 2[1 - (\sigma^2_{X_1} + \sigma^2_{X_2})/\sigma^2_X]$. Formulas that are equivalent to coefficient alpha with $K = 2$ have been attributed to Flanagan (Kelly, 1942), Guttman (1945), Mosier (1941), and Rulon (1939). Both the Spearman–Brown formula and coefficient alpha can be smaller than or larger than the reliability coefficient, if the error score variables are correlated for some or all of X_1 to X_K. (See, for example, Lucke, 2005; Green and Hershberger, 2000; or Raykov, 2001.) Sijtsma (2009) presented a general critique of coefficient alpha.

Equivalence Models

Beginning in the 1960s and continuing through the early 1990s, a series of models collectively referred to as equivalence models were introduced. These models are generalizations of the PMM obtained by relaxing assumptions made in the PMM. Haertel (2006) provides a valuable account of these developments. In this section, We describe these models and present important differences between the implications of these models and the implications of the PMM.

The Essentially Parallel Measurements Model

The name essentially parallel measurements model (EPMM) was coined by Millsap and Everson (1991). The model can be found as early as Kristof (1969). The EPMM is a modification of the PMM in which true score variables for two observed score variables X_k and $X_{k'}$ are related by an additive constant:

$$T_{k'} = c_{k'k} + T_k$$

As shown in Table 1, all of the equalities based on the PMM hold for the EPMM, except the result that the measurements have equal true score means and equal observed score means. The fact that under the EPMM, measurements do not have equal means implies that the measurements are not interchangeable. For example, if several final examinations are available in a course and yield essentially parallel measurements, students would prefer to take the exam that results in the largest mean. Using $\mu_{X_k} = \mu_{T_k}$ and the CTSM, it can be shown that $c_{kk'} = \mu_{X_k} - \mu_{X_{k'}}$, which indicates that scores for measurement k' can be transformed to the scale for measurement k by using $X_k = X_{k'} - \mu_{X_{k'}} + \mu_{X_k}$. This transformation is an example of test linking. Holland and Dorans (2006) describe two types of test linking: scale alignment and equating. Linking is called equating when the transformed scores are interchangeable because the test measures the same construct, the transformed scores are on comparable scales, and the scores are equally reliable. (See Holland and Dorans, 2006, for other criteria required for linking to be equating.) If the measurements conform to the EPMM model and the data are transformed by using $X_{k'} - \mu_{X_{k'}} + \mu_{X_k}$, the scales have been equated because X_k and $X_{k'}$ measure the

same variable, have equal reliability, and the transformed scores have been placed on the same scale.

The Tau-Equivalent Measurements Model and Essentially Tau-Equivalent Measurements Model

The tau-equivalent measurements model (TEMM) is a modification of the PMM in which the assumption of equal error score variances is dropped. Similarly, the essentially tau-equivalent measurements model (ETEMM) is a modification of the EPMM in which the assumption of equal error score variances is dropped. The TEMM and ETEMM were introduced by Novick and Lewis (1967). **Table 1** shows the equality results that do not hold for these two models. A particularly important implication of these models is that different measurements do not have the same reliability coefficient. We will trace the implication of this result for the ETEMM; the same implication applies to the TEMM. Let $X_1 = T_1 + E_1$ and $X_2 = T_2 + E_2$ denote two essentially tau-equivalent measurements. The reliability coefficients for the two measurements are $\rho^2_{X_kT_k} = \sigma^2_T/\sigma^2_{X_k}, \quad k = 1, 2$. The true score variance is the same for each of the two measurements because the true score variables differ by an additive constant. The observed score variances are not equal because the error score variances are not equal. The correlation between the two measurements is $\rho_{X_1X_2} = \sigma^2_T/(\sigma_{X_1}\sigma_{X_2})$ and is not equal to either of the reliability coefficients. In fact $\sigma^2_T/(\sigma_{X_1}\sigma_{X_2})$ is equal to the geometric mean of the reliability coefficients. Therefore the correlation coefficient between two tests that conform to the ETEMM must be larger than the smaller reliability coefficient and smaller than the larger reliability coefficient. It can be shown, for example, that $\rho^2_{X_1T_1} = (\sigma_{X_2}/\sigma_{X_1})\rho_{X_1X_2}$ which provides a basis for computing the reliability coefficient for X_1. The reliability coefficient for X_2 is $\rho^2_{X_2T_2} = (\sigma_{X_1}/\sigma_{X_2})\rho_{X_1X_2}$. Under the ETEMM, the variable with the larger observed score variance has the larger error score variance and, as the expressions for the reliability coefficients imply, has the smaller reliability coefficient. If a test can be split into two halves that conform to the ETEMM, coefficient alpha can be applied to scores on the two half-tests and equals the reliability coefficient for the test scores on $X = X_1 + X_2$ (Novick and Lewis, 1967). If the test can be split into K parts that yield ETEMM measurements then the general form of coefficient alpha is equal to the reliability of the test. The Spearman–Brown formulas do not apply to these models because the reliability coefficients are not the equal for all measurements. Finally measurements that conform to the TEMM or ETEMM cannot be equated because the measurements do not have the same error score variance. The measurement scales can be aligned, but even after the alignment the scores are not interchangeable because of the differences in error variance. In general, among measurements that conform to the TEMM or ETEMM, the measurement with the smaller error score variance is preferred.

The Congeneric Measurements Model

The Congeneric Measurements Model (CMM), introduced by Joreskog (1971), is the most general of the equivalence models. In the CMM, $X_k = T_k + E_K$, that is, the true score variable is not the same for all measurements. However, $T_k = \lambda_k(T_{k'} - c_{k'})/\lambda_k + c_{k'}$. That is, the true score variable for measurement k is linearly related to the true score variable for measurement k'. Scores on the various measurements can be linked but are not interchangeable because they have different measurement error variances (see **Table 1**). Measurements that conform to the CMM have different reliability coefficients. Consequently, the correlation between two congeneric measurements is not equal to the reliability coefficient of either and the Spearman–Brown formula should not be used. It can be shown that coefficient alpha for a sum of congeneric measurements is smaller than the reliability coefficient for the sum. Contributions to reliability theory under the CMM have been provided by Joreskog (1971), Kristof (1971; 1974), and Feldt (1975). Among others, Feldt (1975) provides contributions for a special case of the CMM in which $\sigma^2_{E_k} = \lambda_k\sigma^2_{\tilde{E}}$ and $\sigma^2_{\tilde{E}}$ is the variance of $\tilde{E} = E_1 + \cdots + E_K$.

Lower Bounds to the Reliability of a Composite Variable

Recall that a composite variable is $\tilde{X} = X_1 + \cdots + X_K$, a sum of observed score variables. The observed variables can be separately scored parts of a test that sum to the score on the test. Therefore, the lower bounds provide a method for approximating the reliability of the test from a single administration of the test. Novick and Lewis (1967) showed that a necessary and sufficient condition for coefficient alpha to be equal to the reliability of the composite $\tilde{X}$ is that the measurements conform to the ETEMM. This implies that for the models that are special cases of the ETEMM, that is the PMM, EPMM, and TEMM, coefficient alpha is equal to the reliability of the composite $\tilde{X}$. For more general models, alpha is smaller than the reliability coefficient for the composite $\tilde{X}$. These claims are based on the assumption that the error variables for the components of $\tilde{X}$ are uncorrelated.

Guttman (1945) introduced six lower bounds to reliability. One of these, λ_3, is equal to α and one of the lower bounds, $\lambda_2 = \{\sigma^2_{\tilde{X}} - (\sigma^2_{X_1} + \cdots + \sigma^2_{X_K}) + \sqrt{[K/K-1][\sigma^2_{\tilde{X}} - (\sigma^2_{X_1} + \cdots + \sigma^2_{X_K})]}\}/\sigma^2_{\tilde{X}}$ is always at least as large as α. Ten Berge and Zegers (1978) introduced an infinite series of lower bounds in which coefficients α and λ_2 are the first two terms and each term in the series is at least as large as the preceding term. According to Ten Berge and Zegers the terms beyond α and λ_2, typically, do not get substantially larger than the first two terms. Bentler (1972) introduced the dimension-free lower bound to reliability. Jackson and Agunwamba (1977) introduced the greatest lower bound (glb) to reliability, a value such that the reliability of $\tilde{X}$ must be at least as large as that value. For example, a glb equal to 0.90 implies the reliability of the test scores is at least 0.90. Unfortunately, when an estimate of glb is calculated from sample data, the estimate is positively biased unless the sample size is very large. Consequently, an estimated glb that is equal 0.90 may be a spuriously optimistic lower bound for reliability and reliability of the composite may be much smaller. This bias has hampered the use of the glb. However, Li and Bentler (2011)

have published corrections to the bias, which may make the glb more useful.

The common factor model for the observed variables $X_1,\ldots,X_K$ is

$$X_k = \mu_k + \lambda_{k1}F_1 + \cdots + \lambda_{kJ}F_J + S_k + E_k$$

where F_1 to F_J ($J < K$) are common factors, S_k is a specific factor, E_k is a measurement error variable, $\lambda_{k1},\ldots,\lambda_{kP}$ are factor loadings, and $\mu_1,\ldots,\mu_K$ are the means of the observed variables. The factor loadings are measures of the relationship between the observed variables and the common factors. A common factor, F_j, is a latent variable and has a relationship with at least two observed variables. The specific factor, S_k, is a latent variable that is only related to X_k. The common factors can be mutually correlated, but are not correlated with either the specific factors or the error variables. The specific factors and error variables are also uncorrelated. Defining $C_k = \mu_k + \lambda_{k1}F_1 + \cdots + \lambda_{kJ}F_J$ as the common part of X_k, we can write $X_k = C_k + S_k + E_k$. Then $\tilde{X} = \tilde{C} + \tilde{S} + \tilde{E}$, where $\tilde{C}$, $\tilde{S}$, and $\tilde{E}$ are the sums of C_k, S_k, and E_k variables, respectively. The composite common part (i.e., $\tilde{C}$) is uncorrelated with the composite specific factor (i.e., $\tilde{S}$) and the error of measurement for the composite (i.e., $\tilde{E}$). Because $\tilde{X} = \tilde{T} + \tilde{E}$, $\tilde{T} = \tilde{C} + \tilde{S}$. That, is the composite specific factor, $\tilde{S}$, is a component of $\tilde{T}$. Because $\tilde{S}$ is uncorrelated with $\tilde{C}$, $\sigma^2_{\tilde{T}} = \sigma^2_{\tilde{C}} + \sigma^2_{\tilde{S}}$ and the reliability coefficient is $\rho^2_{\tilde{X}\tilde{T}} = (\sigma^2_{\tilde{C}} + \sigma^2_{\tilde{S}})/\sigma^2_{\tilde{X}}$. To estimate $\sigma^2_{\tilde{C}} + \sigma^2_{\tilde{S}}$ and the reliability coefficient, it is necessary to estimate the factor loadings, variances of the common factors, covariances of the common factors, and variances of the specific factors. Factor analysis provides a method for estimating these parameters, though in most cases the variances for the specific factors cannot be estimated. When $\sigma^2_{\tilde{S}}$ cannot be estimated, the results of the factor analysis can be used to estimate a lower bound to reliability due to McDonald: $\omega = \sigma^2_{\tilde{C}}/\sigma^2_{\tilde{X}}$ (see McDonald, 1999). Coefficient ω is a lower bound to reliability because $\sigma^2_{\tilde{C}} \leq \sigma^2_{\tilde{T}}$. Revelle and Zinbarg (2009) present examples in which an estimate of ω exceeds the estimate of the glb, a demonstration that raises the issue of whether estimates of ω are positively biased in small samples. Ten Berge and Socan (2007) argue that the glb is preferable to ω because the glb is formulated in terms of true and error score variance whereas ω will only be equal to the reliability coefficient, if $\sigma^2_{\tilde{S}} = 0$.

The equivalence models presented earlier are special cases of the common factor model. All of the equivalence models assume that measures of the same construct have a nonzero loading on only one factor and that there are no specific factors. Thus, for the equivalence models, the common factor model specializes to

$$X_k = \mu_k + \lambda_{kr}F_r + E_k$$

and implies that if all observed variables measure the same true score variable there will be just one factor. If there are several true score variables and each observed score variable measures just one of these, there will be more than one factor in the model, but measures of the same true score variable will have a nonzero loading on only one factor. **Table 2** shows the equations for the equivalence models. In **Table 2**, a k subscript on a mean or on a factor loading means that the parameter is not restricted to be constant across measures of the same construct. The models are presented from the least restrictive model (CMM) to the most restrictive model (PMM). For the CMM, the true score variable is equal to $\mu_k + \lambda_{kr}F_r$. For the other models the true score variable is equal to the restricted form of $\mu_k + \lambda_{kr}F_r$. See Raykov and Marcoulides (2010) for additional information about using factor analysis to estimate reliability coefficients.

Table 2 Equations and restrictions on error variances for five test theory models

Model	*Equation*	*Error score variance*
Congeneric measurements model	$X_k = \mu_k + \lambda_{kr}F_r + E_k$	Not equal
Essentially equivalent measurements model	$X_k = \mu_k + \lambda_r F_r + E_k$	Not equal
Tau-equivalent measurements model	$X_k = \mu + \lambda_r F + E_k$	Not equal
Essentially parallel measurements model	$X_k = \mu_k + \lambda_r F + E_k$	Equal
Parallel measurements model	$X_k = \mu + \lambda_r F + E_k$	Equal

Summary

CTT has a long history with a major focus on the definition of the reliability coefficients; the relationship between reliability and various parameters such as coefficient alpha, λ_2, and ω; the correlation between parallel or nonparallel measurements; the effects of lengthening tests by adding parallel measurements; and the effect of measurement error on correlation coefficients. Despite this long history, two difficult problems in applying CTT are determining the best method for estimating reliability for a given data set and assessing the degree to which applications of CTT produce misleading results when the assumptions of the theory are not met. Despite these problems, CTT remains as the foundation for more complex measurement theories.

Abstract

Combinatorial data analysis (CDA) consists of a collection of methods for confirmatory and exploratory data analyses. The common component of these methods is the use of combinatorial operations, such as permutations or combinations, to either generate reference distributions for a statistic (in the confirmatory case) or optimize some objective function (in the exploratory case). This article especially highlights recent advancements for exploratory CDA applications such as seriation, unidimensional scaling, multidimensional scaling, clustering, and variable selection.

Introduction

Combinatorial data analysis (CDA) is a term coined by Arabie and Hubert (1992) that spans several areas of scientific study. Hubert and Arabie (2001) organized their entry for CDA in the first edition of this encyclopedia around two broad subareas: (1) confirmatory combinatorial data analysis (CCDA) and (2) exploratory combinatorial data analysis (ECDA). The CCDA applications are characterized by 'combinatorial computation,' whereby combinatorial methods are used to generate a reference distribution to obtain a *p*-value for an observed statistic. Accordingly, most nonparametric statistical methods, along with most randomization and permutation tests, fall under the CCDA umbrella. The ECDA methods focus on using combinatorial optimization methods to uncover structure and include seriation, scaling, and clustering. Our coverage of CDA tips heavily in favor of ECDA, where considerable methodological advancements have emerged in the past 10–15 years. In addition to coverage of the ECDA methods discussed by Hubert and Arabie (2001), we broaden the scope of CDA to include another important class of problems, namely, variable selection in multivariate statistics.

The structure of our entry is organized into four major sections. Within each of these sections, there are two main subsections: (1) Models and Applications and (2) Methods. Section Confirmatory Combinatorial Data Analysis provides a coverage of CCDA. Section Seriation and Scaling reviews recent methods for problems in seriation and scaling. Section Clustering focuses on combinatorial problems in clustering, Section Variable Selection discusses the role of combinatorial optimization in the development of variable selection for multivariate statistical applications. The article concludes with a brief summary.

Confirmatory Combinatorial Data Analysis

The notion of generating reference distributions to measure the significance of an observed statistic dates back to the 1930s. More recent and extensive treatments of CCDA topics are provided by Edgington (1995), Hubert (1987), and Mielke and Berry (2001). Hubert and Arabie (2001) organized their coverage of CCDA along the topics of linear assignment and quadratic assignment. One of the inherent advantages of this organization is that linear and quadratic assignment together contain many interesting applications, such as rater agreement, regression, and ANOVA. We also use the linear assignment and quadratic assignment distinction, but also include a section on multinomial models that are widely used in the analysis of contingency tables.

Models and Applications

Linear assignment

The linear assignment model is, for all intents and purposes, a matching model. Given an $n \times n$ matrix, the observed statistic is typically an index measure computed as the sum of the main diagonal elements, and the reference distribution is obtained by recomputing the index for permutations of the columns of the matrix. Hubert and Arabie (2001) note that Pearson's product–moment correlation and Cohen's kappa are among the applications of linear assignment.

Quadratic assignment

The quadratic assignment model assumes two $n \times n$ matrices as input. The observed statistic is typically an index measure computed as the sum of elementwise products of the two matrices. The reference distribution is obtained by recomputing the index for permutations of the rows and, simultaneously, the columns of one of the two matrices while holding the other matrix fixed. Hubert and Arabie (2001) observe quadratic assignment applications such as one-way ANOVA and spatial autocorrelation. We note that quadratic assignment methods have been increasingly popularized in the past 10–15 years because of their role in hypothesis testing within the context of social network structures.

Multinomial (fixed-marginal) models

An exact permutation test for a variety of contingency table statistics can be developed using the principles of fixed-marginal tests (see Hubert, 1987 for a discussion). An 'observed' contingency table is constructed and established and the appropriate statistic is computed. The marginal frequencies of the table are the row and column sums. All contingency tables yielding the same fixed marginal frequencies as the observed table are generated, and their probabilities are computed by

the multinomial distribution. Summing the probabilities for tables that yield a statistic greater than or equal to the observed statistic produces an exact p-value.

Methods

Exact p*-values*

Complete enumeration of the entire reference distribution enables an exact p-value to be established for the observed statistic. This approach becomes impractical as the number of objects increases. For example, evaluation of all $n!$ permutations might be computationally feasible for $n = 10$, but probably not for $n = 15$. It might also be possible to explicitly evaluate all contingency tables with the same fixed marginals, but computational feasibility of this approach depends on the number of objects and the dimensions of the contingency table. Some authors have shown that partial enumeration strategies can often enable exact p-values to be established without explicit generation of the entire reference distribution.

Resampling

A more common approach to obtaining p-values is to randomly sample from the set of all possible configurations to obtain the reference distribution. Hubert (1987), for example, often uses a sample size of 10 000 to obtain the reference distribution, which is more than sufficient to perform a test at, say, $\alpha = .05$ or $\alpha = .01$. The key takeaway here is that even when computation of the exact p-value is possible, resampling might be perfectly sufficient for the analyst's hypothesis testing needs.

Distributional tests

Another approach for estimation of p-values is to use asymptotic distribution theory to estimate means and variances for the various indices. Although this approach can be effective when sample sizes are large, its utility is diminished for small sample sizes. Moreover, the derivation of the variance for some index measures is a nontrivial task.

Seriation and Scaling

There are a variety of problems in the social sciences that require the identification of a permutation or sequence of the objects to uncover underlying structure based on proximity information among pairs of objects. These are known as *seriation* problems. Unidimensional scaling is a closely related problem that incorporates the additional requirement of the specification of distances between pairs of objects in the permutation in an attempt to closely recover dissimilarity information among the objects. This process can also be generalized to multidimensional scaling in the city-block metric (Hubert et al., 2006).

Models and Applications

Paired comparison ranking

Paired comparison ranking is an important type of seriation problem that requires the sequencing of objects based on information in an asymmetric proximity matrix. The objective of the problem, which also has application to triangularization of input–output matrices in economics, is to find a reordering of the rows and columns that maximizes the sum of the matrix elements above the main diagonal in the reordered matrix.

Gradient-based seriation

In some applications, it is desirable to obtain a permutation of the rows and columns of a matrix such that the elements in the reordered matrix exhibit a desirable pattern. These patterns typically involve either nonincreasing or nondecreasing elements when moving away from the main diagonal within rows or columns. An excellent discussion of gradient-based seriation is provided by Hubert et al. (2001, Chapter 4), who provide a number of possible indices that can be used for this procedure.

Unidimensional scaling

The goal of unidimensional scaling is to place a set of n objects along a continuum such that distances between the pair of objects approximate, as closely as possible, the dissimilarities between pairs of objects in a set of observed proximity data. Typically, the quality of the fit is measured by a least squares loss function (Brusco and Stahl, 2005; Hubert et al., 2001; Chapter 4); however, a least absolute deviation loss function can also be used.

Multidimensional city-block scaling

The principles of unidimensional scaling can be generalized to multidimensional scaling in the city-block metric (Hubert et al., 2006). The only difference is that permutations of the objects are established for two or more dimensions, and the computed distances between pairs of objects are the sum of the distances across multiple dimensions.

Methods

In our classification of methods for problems of seriation and scaling, we distinguish between *exact* methods and *approximation* (or heuristic) methods. Exact methods are guaranteed to provide a globally optimal solution for the underlying discrete optimization problem. For small problems, this can be accomplished using exhaustive enumeration of all possible solutions, whereas partial enumeration strategies such as dynamic programming and branch-and-bound are often feasible for large problems. Approximation procedures do not afford the guarantee of globally optimal solutions, yet they often provide globally optimal solutions for small problems and remain scalable for larger ones.

Exact methods

Dynamic approaches for seriation and unidimensional scaling are based on pioneering work in electrical engineering. These approaches have been adapted for seriation of asymmetric matrices within the context of analysis of paired comparison data, as well as for unidimensional scaling (see Hubert et al., 2001, Chapter 4). Dynamic programming is a fast and reliable alternative for seriation of problems with up to about 30 objects. One of its most desirable properties is its lack of sensitivity to the degree of 'structuredness' of the input proximity data. Nevertheless, beyond 30 objects, the

computer storage required for dynamic programming makes it computationally infeasible for most hardware platforms.

Branch-and-bound algorithms have been developed for seriation of asymmetric proximity data within the context of paired comparison ranking, as well as unidimensional scaling. A review of these algorithms, along with other applications, is provided by Brusco and Stahl (2005, Chapters 7–11). Linear and integer programming approaches for seriation of asymmetric matrices have proved successful for many years. In fact, quite sizable problems (100 or more objects) can often be solved exactly using current commercial software programs. The computational evidence for using integer programming to solve gradient-based seriation problems and least-absolute deviation of unidimensional scaling problems is less encouraging.

Approximation methods

Although exact methods for seriation, unidimensional scaling, and multidimensional scaling are feasible for some problems of practical size, heuristics are required for larger problem instance. De Soete et al. (1988) proposed a general heuristic solution strategy for seriation and unidimensional scaling based on iterative quadratic assignment. This approach has also been adapted for multidimensional city-block scaling. The computational evidence suggests that iterative quadratic assignment works well for modestly sized problems, particularly those where there is some inherent structure in the data.

Simulated annealing has been one of the most popular heuristic approaches for seriation, unidimensional scaling, and multidimensional scaling for the past dozen years. A review of recent simulated annealing approaches for unidimensional scaling, paired-comparison ranking seriation, and other application is provided by Brusco et al. (2008), who also integrated simulated annealing in conjunction with a heuristic implementation of dynamic programming to obtain solutions for large-scale seriation of asymmetric matrices, gradient-based seriation, and unidimensional scaling.

Clustering

The literature on clustering methods is vast and, therefore, it is impossible to provide a comprehensive review within the confines of this treatment of CDA. We will not attempt to cover the literature on mixture-model clustering, which tends to use smooth optimization procedures rather than combinatorial ones. Moreover, we will only address several areas of combinatorial clustering literature that we believe are apt to be of continued or emerging importance in the social sciences literature. In the following Section Models and Applications, we focus on four classes of models and applications of combinatorial clustering in the social sciences: (1) distance-based clustering of metric data, which is most common in the literature; (2) clustering of nonmetric data; (3) clustering of social network data; and (4) multiobjective clustering.

Models and Applications

Distance-based clustering of metric data

In many applications, researchers have measurements for N objects (customers, students, patients, etc.) on each of P metric variables. The most common clustering approach for such data is K-means clustering (see Steinley, 2006, for a review), which seeks to find a partition of the objects that minimizes the sum of the squared Euclidean distances of the objects to their cluster centroids. In this context, the cluster centers are virtual because they are variable means that do not necessarily correspond to any given object. A closely related option is to cluster the cases to minimize the sum of the distances of each object from an 'exemplar' object in its cluster (Kaufman and Rousseeuw, 2005). When using the exemplar clustering model, the cluster centers are actual objects. Moreover, exemplar-based clustering methods tend to be more general in nature and can be used for a broad range of similarity and dissimilarity data.

Clustering nonmetric data

Combinatorial methods for clustering nonmetric data also have an extensive history, with their roots dating back to literature on majority rule and social choice. Clique partitioning is a popular approach that is based on the establishment of binary equivalence relations among the categorical measures. A partition is sought that minimizes deviation in a least squares sense. The formation of dissimilarity data based on any number of relations also enables the implementation of minimum-diameter partitioning, which seeks to establish compact partitions by minimizing the maximum dissimilarity between any two objects in the seam cluster. This approach is analogous to the nonhierarchical clustering analog of complete-line hierarchical clustering and is closely related to the graph-coloring problem.

Blockmodeling of social network data

The substantial interest in social network data during the past 10 years creates the need for a special treatment of this topic. Although network data can be analyzed by establishing dissimilarity measures among the nodes of the network and using standard hierarchical and nonhierarchical methods, Doreian et al. (2005) have proposed a more elegant approach known as 'generalized blockmodeling.' For one-mode networks, blockmodeling can be as simple as establishing a bipartition of the nodes of the network, such that one cluster is a highly interconnected core and the other is a weakly interconnected periphery. However, blockmodeling can also accommodate much more formal multiple cluster approaches, as well as different relations based on regular, structural, and other types of equivalence. The blockmodeling of signed networks and two-mode networks has also received extensive attention.

Methods

Exact methods

Considerable progress has been made in the development of exact solution procedures for K-means clustering problem. Although dynamic programming methods (Hubert et al., 2001; Chapter 3) are limited to problems with roughly 30 objects, branch-and-bound methods have successfully solved K-means clustering problems with up to 150 objects (Brusco and Stahl, 2005; Chapter 5). New mathematical programming formulation and solution techniques for

clustering problems have provided even more impressive results for both *K*-means (Aloise et al., 2012), solving problems with thousands of objects. When used in conjunction with heuristics, Lagrangian relaxation, and/or column generation, branch-and-bound algorithms can also successfully solve large instances (several hundred objects or more) of the *K*-median problem. Mathematical programming approaches can also be gainfully employed for other clustering problems, such as clique partitioning.

Approximation methods

There is an assortment of heuristic procedures that are interchangeably referred to as *K*-means clustering methods (Steinley, 2006). These procedures typically iterate between phases of cluster centroid computation and object reassignment until convergence. These heuristics can be gainfully augmented with exchange algorithms. In fact, there is evidence to suggest that using thousands of restarts of the *K*-means heuristic from different seed points can yield performance with much more sophisticated metaheuristics. Similar types of exchange algorithms are also effective for *K*-medoids clustering.

Metaheuristics for clustering problems have abounded during the past couple of decades. For *K*-means clustering, metaheuristics include, but are not limited to, simulated annealing, tabu search, genetic algorithms, and variable neighborhood search. Brusco and Steinley (2007) provide a review and comparison of these heuristics. The same type of heuristics have also been gainfully employed for *K*-medoids clustering and clique partitioning.

Variable Selection

In many multivariate statistical applications, researchers are faced with a large set of potential variables. Moreover, it has long been recognized that, in many applications, at least some of the potential variables will not contribute to the data analysis and might even be detrimental. The problem of variable selection is an inherently combinatorial one because of the exponential growth in the number of subsets as a function of the number of candidate variables. When there are P candidate variables, there are 2^P possible subsets of variables.

Models and Applications

Regression

The selection of an appropriate subset of variables in regression is important regardless of whether the principal focus of the application is description or prediction. In studies where the emphasis is on describing which variables contribute most to explanation of the dependent variable, the presence of multicollinearity can make it difficult to disentangle relative predictor importance. In the case of predictive applications, noisy variables can lead to overfitting and poor prediction of new cases. Although most of the variable selection literature pertains to standard ordinary least squares (OLSs) regression, adaptations have also been designed for logistic regression and polynomial regression.

Discriminant analysis

As in the case of regression, there is often a distinction made between descriptive and predictive applications. Although most of the variable selection literature in discriminant analysis centers on the predictive side, the measurement of predictor contribution may also be relevant in some applications.

Factor analysis and principal component analysis

There is a tendency to conclude that variable selection is not particularly relevant for factor analysis or principal component analysis, which are dimension reduction approaches in their own right. However, it is important to recognize that the number of factors extracted, the loadings, and the factor scores are all contingent on the variables entered into the model. Recent research has shown that considerable improvement in interpretability can often be realized by applying variable selection methods prior to running a principal component or factor analysis.

Cluster analysis

It is long been recognized that even a few irrelevant variables can substantially distort the recovery of structure in a cluster analysis. Not surprisingly, this has led to a substantial effort devoted to the development of variable selection methods for clustering.

Methods

Exact methods

Exact solution procedures for variable selection fall into two major categories: (1) all-possible-subsets methods and (2) branch-and-bound methods. All-possible-subsets methods are precisely what the name implies. Solutions for all 2^P variable subsets are analyzed and the best subset (or, possibly, the top 5 or 10 subsets) based on the appropriate objective criterion is stored further analysis. Although this option was once computationally daunting, it is now often feasible for multivariate statistical applications where P is in the low 20s or less. Moreover, in some applications, such as regression, there are computational aspects of the problem that can be exploited for additional efficiency.

In some applications, there is a monotonicity property for the objective function that enables branch-and-bound strategies to be gainfully employed. The fact that the R^2 measure in regression cannot decrease when a predictor is added is a simple example. One of the most important contributions in this respect was Furnival and Wilson's (1974) branch-and-bound method for multiple regression. This algorithm has been the underpinning for more recent adaptations for regression, as well as extensions for polynomial regression, discriminant analysis, and principal component analysis.

Approximation Methods

For applications where the monotonicity property of the objective function does not hold, or P is too large to enable branch-and-bound methods, approximation procedures are necessary. Among the earliest heuristic procedures are forwards selection, backward elimination, and stepwise methods. Forward selection begins with an empty set of selected variables, and variables are added one at a time until a stopping

criterion is reached. Backward elimination begins with all variables selected and eliminates variables one at a time until a stopping criterion is reached. Stepwise methods typically combine elements of forward selection and backward elimination in some fashion. Although once the workhorses of variable selection (and still present in some commercial software packages), forward selection, backward elimination, and stepwise methods are now generally considered outmoded approaches.

Transfer and exchange algorithms for variable selection typically evaluate three types of neighborhood search operations: (1) adding, i.e., moving a variable from the unselected to selected subset of variables; (2) dropping, i.e., moving a variable from the selected to unselected subset of variables; and (3) interchanging, i.e., swapping a variable in the selected subset with one from the unselected subset. Although effective in their own right, these algorithms often form the engine of more sophistical search procedures such as simulated annealing, tabu search, genetic algorithms, and variable neighborhood search.

Metaheuristic approaches have been gainfully employed for variable selection in several areas of multivariate statistics. For example, the effectiveness of genetic algorithms, tabu search, and variable neighborhood search have been evaluated within the context of discriminant analysis. Simulated annealing, tabu search, and variable neighborhood search have been used for regression applications. A number of metaheuristic approaches have also been evaluated for principal component analysis.

Summary

In our preparation of this article for CDA, we have sacrificed a considerable amount of depth for any given topic area in order to achieve greater breadth in the topic areas covered. In closing, we offer one final treatment of an emergent method in ECDA, namely, multiobjective CDA, which has become increasingly common in the past 10–15 years. Multiobjective CDA applications abound in seriation and scaling, as well as clustering (see, for example, Brusco and Stahl, 2005, Chapters 6 and 11). Moreover, multiobjective programming can sometimes offer a linchpin between seriation and clustering. It seems likely that continued advancements in computational hardware and software, along with the need to obtain solutions that accomplish multiple objectives, will result in multiobjective methods playing a greater role in future applications.

Psychometrics: Item Response Theory

David Thissen, The University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Item response theory (IRT) comprises a set of generalized latent variable models designed specifically for data arising from educational and psychological tests and questionnaires. IRT is used for item analysis and scale development and provides the statistical underpinnings for computerized adaptive testing. There are IRT models for items with either dichotomous or polytomous response formats on scales that measure one or more dimensions of individual differences.

In contemporary statistical parlance, item response theory (IRT) comprises a set of generalized latent variable models (Skrondal and Rabe-Hesketh, 2004) designed specifically for data arising from educational and psychological tests and questionnaires (Bock and Moustaki, 2007). While there are many meanings of the term *latent variable* (see Skrondal and Rabe-Hesketh, 2004: Chapter 1), in the context of IRT *latent variable* refers primarily to a hypothetical construct that explains the observed covariation among the item responses, and secondarily to *latent responses* that are continuous variables underlying observed categorical responses. The models are *generalized* in the sense that they use nonlinear link functions to relate (usually linear) functions of the underlying continuous latent variables to the observed responses. Closely related models with discrete latent variables are referred to as *latent class models*.

Current uses of IRT include item analysis, scale development, detecting group differences in item responses, estimating scores for computerized adaptive testing (CAT), accounting for violations of local dependence with the use of testlets, as well as developing an understanding of the psychological response process underlying people's answers to academic, social, and personality questions.

Intellectual History

Latent variable models have only relatively recently become respectable subjects of study in the field of statistics; however they have a long history of development in psychology and the social sciences. Indeed, the use of the terms *manifest data* for observed responses, and *latent continuum* for the underlying unobserved variable, may have originated with Lazarsfeld (1950: p. 367), who wrote that "We shall now call a *pure test* of a continuum x an aggregate of items which has the following properties: *All interrelationships between the items should be accounted for by the way in which each item alone is related to the latent continuum*." (Emphasis in the original.) We now say that a 'pure test,' in Lazarsfeld's language, is a test in which the item responses fit well with a model with the properties of *unidimensionality* and *local independence*.

The intellectual antecedents of IRT within quantitative psychology predate even the distinction between latent variables and manifest data. The *normal ogive* model for dichotomous data (Lord, 1952), based on theory summarized by Lord and Novick (1968: pp. 370–371), has its roots in Thurstone's (1925, 1927) ideas about scaling tests and psychological stimuli. The intellectual history of IRT models has been summarized by Bock (1997) and Thissen and Steinberg (2009). Embretson and Reise (2000) and DeMars (2010) have offered introductory texts on IRT.

Models for Dichotomous Responses

A prototypical IRT model is the two-parameter logistic (2PL) model for dichotomous responses. Common notation for a logistic *trace line* that 'traces' (Lazarsfeld, 1950: p. 364) the probability of endorsement of item i is

$$T(u_i = 1) = \frac{1}{1 + \exp[-a_i(\theta - b_i)]}, \qquad [1]$$

in which u_i is the item response (1 for correct or endorsement, 0 otherwise), θ is the latent variable being measured, and a_i and b_i are two item parameters – hence, the 2PL. The a parameter is referred to as the *discrimination* or *slope* parameter. The slope parameter is usually positive; its magnitude indicates the strength of the relation between the item response and θ. Equation [1] is written in *slope-threshold* form, in which the threshold parameter b_i is the value of the latent variable θ at which a person has a 50-50 chance of endorsing the item.

The upper panel of **Figure 1** shows trace lines for four dichotomous items in a format that is modeled loosely after Guilford's (1936: p. 427) **Figure 1**, in the sense that it uses the axis labels 'scale of ability' and 'probability of success.' The modern notation θ is added to the abscissa label, which is marked in standard units. Three of the curves are 2PL trace lines: The curve marked A is for a relatively easy ($b = -1.75$), highly discriminating ($a = 3$) item; that marked B is for a slightly easier ($b = -1.25$), less discriminating ($a = 1$) item; and the one marked D is for a more difficult ($b = 1$), similarly less discriminating ($a = 1$) item. The curve marked C is an example of a three-parameter logistic (3PL) trace line. The 3PL model adds a parameter that represents the probability that individuals at low levels of θ may respond correctly or positively, as they do by guessing on multiple choice items. For the item marked C in **Figure 1**, the guessing level $g = 0.2$, the asymptotic level of the curve on the left; setting aside guessing, the item is of moderate difficulty ($b = 0$), and it is relatively discriminating ($a = 2$).

Figure 1 Upper panel: Trace lines for the positive response for four dichotomous items: A, B, and D are two-parameter logistic trace lines, and C is a three-parameter logistic trace line. Lower panel: The information functions for the four items with trace lines in the upper panel, and the total information for the four items.

From a statistical point of view, the crucial aspect of IRT models is that the unobserved variable accounts for the observed interrelationships among the item responses. That means that, given (or *conditional on*) any particular value of the latent variable θ, the item responses are independent; this is usually called the assumption of *conditional independence* or *local independence*. Then the probability of a vector of item responses $\mathbf{u} = [u_1, u_2, \ldots u_I]$ from a particular person for a collection of items indexed by i is

$$P(\mathbf{u}) = \int \left[\prod_i T(u_i) \right] \phi(\theta) \mathrm{d}\theta. \qquad [2]$$

The term $\phi(\theta)$ represents the population distribution of θ, and is usually assumed to be Gaussian. Maximum likelihood (ML) estimation of the item parameters involves choosing their values for all items such that the joint probability (likelihood) of all of the observed item responses from all persons is maximized. The item parameters are embedded in $T(u_i)$ in eqn [2].

IRT provides a detailed quantitative description of each item in the form of the item parameters; these descriptions are useful in test and questionnaire assembly, and in test scoring (Thissen and Wainer, 2001). A very useful derivative function of the item parameters is the item information curve (Birnbaum, 1968); the lower panel of **Figure 1** shows the information functions for the four items with trace lines in the upper panel. The ordinate for the curves in the lower panel is the amount of information (in the likelihood sense) provided by each item at each level of θ. For the 2PL or 3PL model, each information curve has a peak at the value of b; their heights are proportional to the squared value of the a parameter. The information provided by a test is the sum of the information curves for its items, so information curves can be used in test assembly to construct tests with a desired level of information, or measurement precision, at any value, or for any range, of the latent variable.

Models for Polytomous Responses

Samejima's model (1969) for graded item responses is often applied to the analysis of items that are accompanied by Likert-type response scales. The model for an item with K ordered response alternatives $k = 0, 1, 2, \ldots K - 1$ is

$$T(u_i = k) = T^*(u_i = k) - T^*(u_i = k + 1), \qquad [3]$$

in which $T^*(u_i = 0) = 1$ and $T^*(u_i = K) = 0$. $T^*(u = k)$ is the trace line describing the probability that a response is in category k or higher, for each value of the underlying construct. The probability that a response is in a particular category (k) is the probability of observing category k or higher minus the probability that the response is in a higher category. The logistic version of the model is

$$T(u_i = k) = \frac{1}{1 + \exp[-a_i(\theta - b_{ik})]} - \frac{1}{1 + \exp[-a_i(\theta - b_{ik+1})]}. \qquad [4]$$

The slope or discrimination parameter (a) has the same meaning as it does for the 2PL model, and the b_k parameter is the threshold for a category or higher. The value of b_k is the point on the construct axis at which the probability that the response is in category k or higher passes 50%. **Figure 2** shows trace lines from Samejima's (1969) graded model for five Likert-scale responses to an attitude item; for this hypothetical item, $a = 2$ and the four b values are -1.5, -0.5, 0.0, and 1.75.

The statistical model for a collection of polytomous responses remains the same as for dichotomous items; the polytomous trace lines represented by eqn [4] are substituted in eqn [2] to yield a likelihood function that may be used in parameter estimation. Indeed, dichotomous and polytomous items may be mixed in a single test, and analyzed and scored together. There are other models for graded responses, and even for nominal responses with no order specified a priori; chapters summarizing many such models are in volumes on

Figure 2 Trace lines from Samejima's (1969) graded model for five Likert-scale responses to an attitude item.

the subject edited by van der Linden and Hambleton (1997) and Nering and Ostini (2010).

Compensatory Multidimensional Item Response Theory

Until relatively recently, applications of IRT were limited to measurement of a single construct, using models in which θ is unidimensional. This was largely a computational limitation; the conceptual generalization of IRT to *multidimensional item response theory* (MIRT) has been the subject of active research for several decades. Reckase (2009) has provided a book-length summary of research on the topic. Advances in computing and algorithms for statistical parameter estimation have made MIRT applications practical.

IRT becomes MIRT when more than one latent variable is required to account for the observed pattern of covariation among item responses. It is conventional to refer to the collection of several latent variables as $\boldsymbol{\theta}$; the bold typeface indicates that $\boldsymbol{\theta}$ represents a vector with as many values as there are latent dimensions. The most commonly used MIRT models are *compensatory*; they assume that the probability of an item response depends on a linear combination of the component values of $\boldsymbol{\theta}$. It is convenient to represent that linear combination using vector multiplication, in which $\mathbf{a}'\boldsymbol{\theta} = a_1\theta_1 + a_2\theta_2 + \cdots + a_p\theta_p$ for a p-dimensional latent variable. Using that notation, the trace surface for the multidimensional generalization of the 2PL model is

$$T(u_i = 1) = \frac{1}{1 + \exp[-(\mathbf{a}_i'\boldsymbol{\theta} + c_i)]}. \qquad [5]$$

Here T is the surface over the $\boldsymbol{\theta}$ (hyper)plane that traces the probability of a correct or positive response ($u_i = 1$) to item i. For two-dimensional models, $\boldsymbol{\theta}$ is a two-dimensional plane with values of θ_1 from low to high in one direction, and values of θ_2 from low to high in the other direction; T is a surface that rises from zero (for low values of θ_1 and θ_2) to one (for high values of θ_1 or θ_2 or both). Models with more than two latent dimensions are difficult to visualize.

Comparing eqn [5] with eqn [1], the only difference is that the notation $\mathbf{a}'$ represents a vector of as many slope or discrimination parameters as there are dimensions, and $\boldsymbol{\theta}$ is a vector of latent variable values of the same dimensionality. This MIRT model adds one more parameter (one more a value) for each additional dimension. The a parameters each measure the degree of relationship of the item response with the corresponding dimension of $\boldsymbol{\theta}$ (that is, with each construct). The scalar-valued parameter c is an intercept parameter that reflects the overall probability of endorsement of the item. In contrast to the unidimensional 2PL model, an alternative parameterization with a threshold parameter is more difficult to interpret, because for MIRT models the location of $T = 0.5$ is a line for a two-dimensional model, or a (hyper)plane for higher dimensional models – there is no scalar-valued threshold.

Compensatory MIRT models are factor analysis models for categorical item response data, or *item factor analysis* models (Bock et al., 1988; Bartholomew and Knott, 1999; Bock and Moustaki, 2007; Wirth and Edwards, 2007). The differences between MIRT and factor analysis involve the use of nonlinear models for the probability of a categorical item response in MIRT vs linear models for continuous scores in factor analysis, and the fact that the regression parameters measuring the association between the observed variables and the latent variables are estimated as a parameters in MIRT and *factor loadings*, λ, in factor analysis. The former is unavoidable given the nature of the observed data; the latter is a matter of convention.

Noncompensatory Multidimensional Models

In the compensatory models described in the preceding section, the combination rule for a positive response is that the respondent may be high on one *or* another of the latent variables. An alternative model formulation is based on the idea that an item response may depend upon two or more latent variables, and both (or all) must be high to observe a positive response. This formulation yields models in which probabilities of success on the component tasks are multiplied to obtain the probability of overall success; such multiplicative models have most often been called *noncompensatory* models, although Reckase (2009: p. 79) uses the term *partially compensatory*.

As an example of such models for cognitive tests, Embretson (1997) summarizes research on the *General Component Latent Trait Model*, which was designed for cognitive items with *components* or *subtasks*, all of which must be completed for a correct response. An example from the social measurement domain is the *two decision model* (Thissen-Roe and Thissen, 2013) for Likert-type responses in contexts in which individual differences in a tendency to select extreme alternatives may be one of the factors underlying Likert-type scale responses.

Noncompensatory (or partially compensatory) models, like the two mentioned above, have generally been developed for specific item types and testing contexts. While such specialized models may often be useful in their context, they are not intended for general purpose item analysis.

Parameter Estimation

Bock and Aitkin (1981) provided an elegant and practical procedure for item parameter estimation; their algorithm is currently the most commonly implemented in computer software for item calibration, because it is efficient for large numbers of persons and items. Skrondal and Rabe-Hesketh (2004) described a general framework integrating IRT with multilevel models, structural equation models, and longitudinal models, and procedures that may be used to compute ML estimates for complex models that are combinations of all of those. This more general conception is theoretically elegant but computationally intensive, so it is limited to problems with relatively small numbers of variables. Skrondal and Rabe-Hesketh's (2004): Chapter 6 includes a detailed review of virtually all extant ML estimation procedures from a statistical perspective. Bock and Moustaki (2007) provide a similarly general framework for IRT and MIRT models with covariates, and the use of the Bock–Aitkin

EM (Expectation-Maximization) algorithm to estimate the parameters of more elaborate models.

An increasingly widely used alternative to ML estimation is Bayesian estimation using Markov chain Monte Carlo (MCMC) algorithms. Albert (1992) provided the first MCMC algorithm for estimation of the parameters of the normal ogive model, using *data augmentation*, which is one common approach to MCMC estimation for latent variable problems. Patz and Junker (1999a,b) described MCMC algorithms based on *Metropolis–Hastings within Gibbs* sampling, the other common approach to complex MCMC estimation, for the 2PL, 3PL, and other models. An advantage of Bayesian MCMC estimation is the relative ease with which the parameters of more complex models may be estimated. This advantage has been used in recent developments of *testlet response theory* (Wainer et al., 2007) to provide estimates for item response models with an additional parameter that absorbs and corrects for local dependence that may appear on tests that include clustered items.

Scoring Tests Using IRT

In the context of IRT, computing scores is taken to be a statistical estimation problem, in which the goal is to provide a point estimate of an individual respondent's location on the θ dimension(s), with an associated statement of (im)precision, or standard error. A commonly used way to do that is to compute a *scale score* as the expected *a posteriori* estimate of θ, or $\mathrm{EAP}[\theta|\mathbf{u}]$, which is notation for the average of the posterior density for the response pattern $\mathbf{u}$. The posterior density is the integrand of eqn [2], in which the trace lines $T(u_i|\theta)$ may be those of any item response model or a mixture of those. The standard deviations ($\mathrm{SD}[\theta|\mathbf{u}]$) are often reported as the standard error of the scale score.

The process of computing the scale score is independent of the particular items presented to the respondent, because it is a function of the product of trace lines associated with the item responses. If one has item parameters for a large collection of items assembled into an *item bank*, in which all of the items are calibrated with respect to the same latent variable θ, subsets of those items may be administered and scale scores computed that are comparable even for persons who responded to mutually exclusive sets of items. Scoring IRT linked alternate test forms and CAT, which can be viewed as the administration of a large number of custom-made alternate test forms, make use of these properties of scale scores.

Chapters 3 and 4 of the volume by Thissen and Wainer (2001) describe in detail the computations underlying EAP $[\theta|\mathbf{u}]$ and other, alternative, estimators; they also describe an algorithm for computing the expected *a posteriori* estimate given the summed score x ($\mathrm{EAP}[\theta|x]$). IRT scale scores for summed scores are sometimes used in testing programs that want to use the properties of IRT and at the same time base score reporting on summed scores, not response patterns.

Psychometrics: Preference Models with Latent Variables

Ulf Böckenholt, Northwestern University, Evanston, IL, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Current psychometric models of choice behavior are strongly influenced by Thurstone's (1927) experimental and statistical work on measuring and scaling preferences. Aided by advances in computational techniques, preference models can now accommodate a wide range of data types and sources of preference variability among respondents induced by diverse factors such as person-specific choice sets or different functional forms for the underlying utility representations. At the same time, these models are increasingly challenged by behavioral work demonstrating the prevalence of choice behavior that is not consistent with the underlying assumptions of these models.

Introduction

Much of human behavior may be viewed as decisions among options or alternatives. Familiar instances are a citizen deciding whether to vote and if so for whom, an investor considering various stock options, or a shopper contemplating different brands in a product category. In addition to these observational settings, choice data may also be collected in experimental studies asking persons to state their preferences for a single option or multiple sets of options. For example, in a market research study, consumers may be shown a set of products with the instruction to choose from them or to rank them.

Choices collected in observational and experimental settings, which are referred to as revealed and stated preference data (Samuelson, 1938), may complement each other. For instance, in an election, votes for political candidates represent revealed choice data. Rankings of the same candidates in a survey shortly before the election are an example of stated choice data. Stated preference data may prove useful both for predicting the election outcome and for providing more information about the preference differences among the candidates than would be available from the election results alone. The collection of stated preference data is also useful in situations when it is difficult or impossible to collect revealed preference data because choices are made infrequently or new choice options offered in the studies are yet unavailable on the market. For example, in taste-testing studies, consumers may be asked to choose among existing as well as newly developed products.

A major challenge in analyzing choice data is that the observed choice outcomes cannot always be interpreted in an unambiguous way. Decisions may be determined not only by the attractiveness of the options, but also by seemingly irrelevant features of the choice environment. For example, contextual features – such as the order and frames in which information about the choice options is presented – have been shown to influence choice outcomes in systematic ways. In addition, characteristics of the decision maker – such as constraints in attention, knowledge, or time and money budgets – can play a significant role in the way information about the choice option is processed. It is not always possible to separate the influence of the different factors related to the choice options, choice situation, and decision maker on the underlying decision processes based on the observed choices alone (Manski, 2007). However, progress can be made in identifying the factors' separate effects by contrasting revealed and stated preference data.

In psychometrics, most preference models for the analysis of choice data have been developed for stated response settings to serve the dual purpose of summarizing choice outcomes and facilitating the forecasting of choices made by decision makers facing possibly new or different variants of the choice options. These models assume both that certain, possibly unobserved, characteristics of the choice options determine which option is selected, and that decision makers differ in their evaluation of these option characteristics. For example, in an election, voters may base their decision on a set of attributes such as integrity and leadership, but differ in the weights they assign to the attribute values for the different candidates. The application of preference models to voting data may reveal these attributes and provide insights about how voters vary in their attribute-specific assessments of the political candidates. This information can also be useful in forecasting how voters may behave if the attributes of the political candidates are changed in some systematic ways.

The strength of the current arsenal of preference models lies in providing parsimonious descriptions of how decision makers perceive and evaluate choice options. This approach is particularly effective when the different sources of individual variability are understood and readily identifiable. The next section reviews these sources of variability and their analysis with regard to preference models. This review emphasizes Thurstone's (1927) choice paradigm, which has been highly influential in the development of preference models, especially in the psychometric, econometric, and transportation literature. Because emphasis is on conceptual issues, technical topics such as sampling, estimation, and inference are not discussed. Related reviews by Böckenholt (2006), Böckenholt and Tsai (2006), Maydeu-Olivares and Böckenholt (2009), and Train (2009) cover the literature on these subjects in more detail.

Valuation of Choice Options

Most preference models are based on the notion of decision utility. This approach infers the value or utility of an option from observed choices and in turn uses this value to explain choices. For example, if a decision maker chooses option j and rejects option k, this behavior is interpreted as indicating that option j

 http://dx.doi.org/10.1016/B978-0-08-097086-8.43082-5

has a higher utility than option k for this person. A number of consistency conditions have been proposed in the literature to characterize choices based on decision utilities (Tversky, 1969). These consistency conditions are important because they allow nontrivial predictions across new choice settings. Consider pairwise choices among the three options j, k, and l. If option j is preferred to option k, and option k is preferred to option l, we expect that option j is preferred to option l when decision makers are consistent in their ranking of preferences. In contrast, the selection of option l in the last paired comparison indicates an intransitive cycle, which suggests a change in valuation or choice strategy.

To determine whether the observed choice outcome is caused by systematic or random factors, Thurstone (1927) promoted an extended version of the decision–utility concept that allowed for stochastic variability in choices. By invoking Fechner's (1860) psychophysical concept of a sensory continuum, Thurstone proposed that choice options can be represented along a continuum by random variables that correspond to the options' effects on a person's sensory processing. The choice process can be described as the selection of an option with the greatest momentary utility realization. As a result, variability in choices can then be used to recover the features of the underlying utility distribution. Moreover, when the means of the utility realizations are stable across time and situations, consistency conditions such as contraction and expansion consistency across different choice settings can be defined for stochastic preferences (Block and Marschak, 1960). These conditions are supported in many applications, demonstrating the usefulness of this approach in predicting choice behavior for different sets of choice options. However, systematic violations in experimental studies have also been reported, as discussed in the final section.

It is noteworthy that Thurstone (1927) used randomness in choice as a device to represent factors that determine the formation of preferences but are unknown to the observer. This specification was driven by pragmatic considerations to avoid the question of whether a choice process is inherently random or determined by a multitude of different factors that may need to be measured. By not specifying the process by which a person "identifies, distinguishes, discriminates, or reacts to stimuli" (1927, p. 369) and defining it to be exogenous to all the factors that can affect a choice process, Thurstone broadened the applicability of this approach to the modeling of choice data in many different settings. Important to note is that he also utilized these ideas for modeling individual differences in choice behavior by arguing that heterogeneity in individual assessments of the same option can also be described as realizations of an underlying distribution. This approach proved instrumental for the development of econometric choice models (McFadden, 2001). When introducing Thurstone's work to economics, Marschak (1960) coined the term random utility maximization when referring to choice probabilities that result from the maximization of utilities with random elements.

Predicting Choices

Typically, stated choice data are collected in the form of incomplete and/or partial rankings. Incomplete ranking data are obtained when a decision maker considers only a subset of the choice options. For example, the method of paired comparison presents two choice options at a time, and the decision maker is asked to select the more preferred one. In contrast, in a partial ranking task, a decision maker is confronted with all choice options and asked to provide a ranking for a subset of the options. For instance, in the best–worst method, a decision maker is instructed to select the best and worst options from the offered set of choice options. Both partial and incomplete approaches can be combined by offering multiple distinct subsets of the choice options and obtaining partial or complete rankings for each of them. Pick-any, constant-sum, and ordinal versions of paired comparison and rankings are alternative methods for collecting stated preference data (Bock and Jones, 1968; David, 1988; Louviere et al., Hensher and Swait, 2000; Marshall and Bradlow, 2002).

We define a population P of decision makers ($i \in P$) and a finite set C of choice alternatives ($j \in C$). For each decision maker and choice alternative, a vector $\mathbf{x}_{ij}$ of observed variables is available that partially describes the pair (i,j). The underlying momentary utility of option j to person i is denoted by υ_{ij} and is a function of the observed and unobserved attribute values. In this section, distributional assumptions are made to capture the variation of the unobserved attribute values and preference differences among the decision makers. In combination with a decision rule for selecting an option, the utilities determine the options' choice probabilities. As a result, the choice probabilities can be represented by an a priori specified member of a restricted family of functions, which is partially determined by the distributional assumptions about the unobserved attribute values and utility variations.

To be specific, under Thurstone's (1927) approach, the choice of an option j is determined by the unobserved utility assessment, υ_{ij}, which can be decomposed into a systematic and a random part:

$$\upsilon_{ij} = \mu_{ij} + \epsilon_{ij} \qquad [1]$$

where μ_{ij} represents the mean evaluation of option j by person i. In contrast to the option mean, which is assumed to stay the same in repeated evaluations, the random contribution ϵ_{ij} varies from evaluation to evaluation according to some distribution.

In general, the choices made by person i from a single choice set of J options can be summarized by an ordering vector $\mathbf{r}_i$. For instance, $\mathbf{r}_i = (h, j, \ldots, l, k)$ indicates that choice option h is judged superior to option j, which in turn is judged superior to the remaining options, with the least preferred option being k. The probability of observing this ordering vector for person i can be written as

$$\Pr(\mathbf{r}_i = (h, j, \ldots, l, k)) = \Pr[(\upsilon_{ih} - \upsilon_{ij} > 0) \cap \ldots \cap (\upsilon_{il} - \upsilon_{ik} > 0)]$$

More compactly, a $(J-1)\times J$ contrast matrix, $\mathbf{C}_i$, can be defined to indicate the sign of the differences among the ranked options. For example, for the ordering vector $\mathbf{r}_i = (j, l, k)$ of $J = 3$, the corresponding contrast matrix takes on the form

$$\mathbf{C}_i = \begin{bmatrix} 1 & 0 & -1 \\ 0 & -1 & 1 \end{bmatrix}$$

where the three columns of the contrast matrix correspond to the options j, k, and l, respectively.

The distributional assumptions involving ϵ_{ij} determine the probability for each choice pattern. A multivariate probit model is obtained when assuming that the latent judgments $\boldsymbol{\upsilon}_i = (\upsilon_{i1}, \ldots, \upsilon_{iJ})$ of the decision maker i are multivariate normal with mean vector $\boldsymbol{\mu}_i$ and covariance matrix $\boldsymbol{\Sigma}_\nu$. In this case, the probability of observing the ordering vector $\mathbf{r}_i$ is obtained by evaluating a $(J-1)$-variate normal distribution,

$$\Pr(\mathbf{r}_i|\boldsymbol{\mu}_i, \Sigma_\nu) = \frac{|\boldsymbol{\Gamma}_i|^{-1/2}}{(2\pi)^{(J-1)/2}} \int_0^\infty \cdots \int_0^\infty \exp\left\{-\frac{1}{2}(\mathbf{x}-\boldsymbol{\delta}_i)'\boldsymbol{\Gamma}_i^{-1}(\mathbf{x}-\boldsymbol{\delta}_i)\right\} d\mathbf{x}$$

where $\boldsymbol{\delta}_i = \mathbf{C}_i\boldsymbol{\mu}_i$ and $\boldsymbol{\Gamma}_i = \mathbf{C}_i\boldsymbol{\Sigma}_\nu\mathbf{C}_i'$ (Hausman and Wise, 1978).

Typically, in experimental settings, choice options are presented to decision makers in multiple blocks, especially when the set of choice options is large. This multiple-judgment approach is used to simplify the choice task since only a few options need to be considered at a time. It also facilitates studying whether decision makers are consistent in their evaluations of the choice options.

Consider a paired comparison task in which a person is asked to select the preferred option for a subset or all of the pairwise choice sets. Extending [1], the utilities of decision maker i that underlie the pairwise comparison of options j and k, respectively, can be written as

$$\begin{aligned} \upsilon_{ij(k)} &= \mu_{ij} + \epsilon_{ij(k)} \\ \upsilon_{ik(j)} &= \mu_{ik} + \epsilon_{ik(j)} \end{aligned}$$

The terms $\epsilon_{ij(k)}$ and $\epsilon_{ik(j)}$ capture random variations in the choice process, where $\epsilon_{ij(k)}$ denotes the random variation of option j when compared to option k. Thus, the choice between j and k is determined by the sign of the pairwise comparison outcome y_{ijk} computed as the difference between the corresponding utilities

$$y_{ijk} = \upsilon_{ij(k)} - \upsilon_{ik(j)} = \mu_{ij} - \mu_{ik} + \epsilon_{ij(k)} - \epsilon_{ik(j)} \qquad [2]$$

It can be assumed that choices across choice sets are independent or dependent at the individual level. Under independence, one obtains

$$y_{ijk} = \mu_{ij} - \mu_{ik} + \epsilon_{ijk}$$

where $\epsilon_{ijk} = \epsilon_{ij(k)} - \epsilon_{ik(j)}$ and the variability in the choices comes solely from the ϵ's, which are independently distributed given the decision makers' parameters. For multiple comparisons of J options, the latent pairwise judgments of decision maker i can then be written conveniently as a linear model, which simplifies the estimation of this model.

Instead of assuming the random terms, such as $\epsilon_{ij(k)} - \epsilon_{ik(j)}$ and $\epsilon_{ij(l)} - \epsilon_{il(j)}$ in [2], to be uncorrelated, it is also meaningful to consider conditions that may lead to dependencies between them. For example, when an option is compared with two similar options, the utilities in these two comparisons are presumably more correlated than those obtained in a comparison with two less similar options. In this case, the difference in $\epsilon_{ij(k)}$ and $\epsilon_{ik(j)}$ cannot be reduced to the pair-specific term ϵ_{ijk}. This more general approach of allowing for choices among choice sets to be dependent proved useful in understanding intransitive choice behavior in temporal discounting and multiattribute choice applications (Tsai and Böckenholt, 2006; 2008).

Identifiability and Interpretation

Since choosing the most preferred option is assumed to be equivalent to selecting the option with the greatest utility, an important feature of the postulated choice process is its comparative nature. A selected option may be the best one from a set of available options, but it may be rejected in favor of other options that subsequently are added to the set. As choices are inherently comparative, the origin of the utility scale cannot be identified on the basis of the choices alone. One option may be preferred to another, but this result does not allow any conclusions about whether either of the options is inherently attractive or unattractive.

The lack of an origin has important consequences for identifying the underlying utility distributions. In particular, it is not possible to recover all elements of the options' covariance matrix of the unobserved utilities $\boldsymbol{\Sigma}_\nu$ on the basis of choice data. The two covariance matrices $\boldsymbol{\Sigma}_\nu$ and $\Sigma_\nu + \mathbf{d}1' + 1\mathbf{d}'$ are empirically indistinguishable provided the vector $\mathbf{d}$ is chosen so that the resulting covariance matrix is positive-definite (Tsai, 2003). Thus, a row- and column-specific constant can be added to each row and column of the covariance matrix without affecting the choice probabilities. As a result, when estimating $\boldsymbol{\Sigma}_\nu$, constraints need to be imposed to ensure identifiability.

The equivalence relation suggests defining the identified parameters based on the utility differences instead of the utilities of the options. For any contrast matrix $\mathbf{C}$ of rank $J-1$, the corresponding identified parameters for the model with mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}_\nu$ are $\mathbf{DC}\boldsymbol{\mu}$ and $d^{-1}\mathbf{C}\boldsymbol{\Sigma}_\nu\mathbf{C}'$, where $\mathbf{D} = \mathrm{Diag}(\mathbf{S}\boldsymbol{\Sigma}_\nu\mathbf{S}')^{-1/2}$, and d is the (1, 1) element of $\mathbf{C}\boldsymbol{\Sigma}_\nu\mathbf{C}'$. However, other identification constraints can also be chosen that do not involve a contrast matrix. Regardless of the constraints that are being selected, it is important to take into account that the original parameters $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}_\nu$ cannot be recovered from preference data but only a lower dimensional function of them.

The existence of equivalence models for preference data complicates the interpretation of the results since preference models that have the same identified parameters may have substantively different interpretations. Consider the following two ranking models, A and B, for three normally distributed utilities with the respective mean vectors $\boldsymbol{\mu}_A = (2 \quad 5 \quad 0)'$ and $\boldsymbol{\mu}_B = (\sqrt{.8} \quad \sqrt{5} \quad 0)'$ and the covariance matrices $\boldsymbol{\Sigma}_A = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 3 \end{bmatrix}$ and $\boldsymbol{\Sigma}_B = \begin{bmatrix} 1 & .7 & .6 \\ .6 & 1 & .5 \\ .6 & .5 & 1 \end{bmatrix}$. Because these two models yield the same ranking probabilities of (0.038, 0.002, 0.802, 0.148, 0.002, 0.008) for the rank ordering patterns {(1, 2, 3), (1, 3,2), (2,1, 3), (2, 3, 1), (3, 1, 2), (3, 2, 1)}, respectively, they are empirically indistinguishable. However, the interpretation of these two covariance matrices is rather different. Model A has different option variances and zero option correlations. In contrast, model B has equal option variances and nonzero correlations between options. Because of the models' empirical indistinguishability, an interpretation in favor of either model A or model B needs to depend on other factors, such as prior

knowledge or some theory about the underlying choice mechanism. This numerical example also illustrates a frequently overlooked implication in the literature: investigating the model fit of restrictions imposed on either $\boldsymbol{\mu}$ or $\boldsymbol{\Sigma}_{\nu}$ requires taking into account that any evidence in support of this restriction speaks for an entire class of equivalence models and not just for the model form under consideration.
